128 SMOKE INHALATION

Nathan P. Charlton and Mark A. Kirk

HISTORY AND EPIDEMIOLOGY

Smoke is generated as the result of thermal degradation of a material; it is a complex mixture of heated air, suspended solid and liquid particles (aerosols), gases, fumes, and vapors. Particulates and aerosols typically make these thermal degradation products visible to the naked eye, resulting in the black, acrid substance so often thought of as “smoke”; however, thermal decomposition also results in generation of gaseous substances that are invisible to the naked eye. The ever-growing variety of materials used in our environment contributes to the broad spectrum of products present in typical smoke.²⁶ The chemical composition of the parent materials, oxygen availability, and temperature at the time of decomposition determines the combustion products found in smoke (Table 128–1).^{99,112} As a result of these variabilities, specific thermal degradation products resulting from a fire are difficult to predict; in fact, even the composition of smoke is quite variable within the same fire environment.¹¹²

TABLE 128–1. Common Materials and Their Thermal Degradation Products

<i>Products</i>	<i>Thermal Degradation Products</i>
Wool	Ammonia, carbon monoxide, chlorine, cyanide, hydrogen chloride, phosgene
Silk	Ammonia, cyanide, hydrogen sulfide, sulfur dioxide
Nylon	Ammonia, cyanide
Wood, cotton, paper	Acetaldehyde, acetic acid, acrolein, carbon monoxide, formic acid, formaldehyde, methane
Petroleum products	Acetic acid, acrolein, carbon monoxide, formic acid
Polystyrene	Styrene
Acrylic	Acrolein, carbon monoxide, hydrogen chloride
Plastics	Aldehydes, ammonia, chlorine, cyanide, hydrogen chloride, nitrogen oxides, phosgene,
Polyvinyl chloride	Carbon monoxide, chlorine, hydrogen chloride, phosgene
Polyurethane	Cyanide, isocyanates
Melamine resins	Ammonia, cyanide
Rubber	Hydrogen sulfide, sulfur dioxide
Sulfur containing material	Sulfur dioxide
Nitrogen containing material	Cyanide, isocyanates, oxides of nitrogen
Fluorinated resins	Hydrogen fluoride
Fire retardant materials	Hydrogen bromide, hydrogen chloride

Smoke inhalation is a complex medical syndrome involving diverse toxicologic injuries, making care of smoke-injured patients very challenging. In fact, smoke inhalation—not burns—is the leading cause of death from fires. However, cutaneous burns found concurrently with smoke inhalation complicate airway management and fluid resuscitation, and

increase the risk of infection. Consequently, burn victims with smoke inhalation injury have higher morbidity and mortality than those with burns alone.^{36,138}

Disastrous fires are a frequent reminder of the role of inhalation injury in fire deaths. Throughout the United States, a fire department responds to a fire every 23 seconds.⁶⁷ In 2011, the National Fire Protection Agency reported 1,389,500 fire incidents in the United States, with 3005 fire deaths and 17,500 fire injuries.⁶⁷ On average, a civilian fire death occurred every 208 minutes and a civilian injury from a structural fire occurs every 30 minutes.

Compared with other industrialized countries, the United States has one of the highest rates of fire-related deaths in the world.⁴ An estimated 50% to 80% of these deaths result from smoke inhalation rather than dermal burns or trauma.^{13,58,99,158} More than 30% of patients hospitalized in burn units develop complications of concomitant pulmonary injury, and 75% of these patients die.^{61,139} Data from the World Health Organization demonstrate that indoor smoke from heating and cooking fuel is one of the four most common causes of death and disease in developing countries, resulting in an estimated 3.5 million deaths worldwide in 2010.^{12,79}

Fire injuries may result from an array of inhaled toxic xenobiotics and/or thermal burns. Before 1942, toxic inhalation was not considered in the etiology of morbidity and mortality of structural fire victims. However, in that year, a fire at the Coconut Grove Night Club in Boston resulted in a number of fatalities in which victims had no cutaneous burns. This led to the observation that toxic gases are generated in typical structure fires and may result in significant pathology.¹¹¹ From 1955 to 1972, death from smoke inhalation injury increased threefold and was attributed to abundant use of newer synthetic materials for building and furnishings.¹³ Despite improved firefighting resources, mass casualties from smoke inhalation continue. A fire in a crowded Rhode Island nightclub on February 20, 2003, killed 100 people and injured more than 200 people, with the majority suffering from smoke inhalation.³² On December 31, 2004, a fire at a nightclub in Argentina killed 175 people and injured more than 700. Most of the victims died of smoke inhalation.³ On November 24, 2012, a fire swept through the lower floors of a Bangladesh garment factory, killing 112 and trapping many others on the top floors until rescuers arrived. Hundreds of those trapped above the blaze sustained inhalation injuries.¹⁴⁷ More recently, at least 230 people died in a nightclub fire in Brazil when a fire ignited above the concert stage. Smoke inhalation resulted in many of the deaths and forced many others to seek medical treatment.¹³² In 2010, a total of 29 catastrophic fires claimed 175 lives in the United States.⁴ Interestingly, in 2011, explosions caused an unusually high number of catastrophic fires in the United States.⁴ These statistics highlight the complexity of fire victims with the potential for victims to have any combination of inhalation injury, burns, and trauma.

PATHOPHYSIOLOGY

Toxic combustion products are classified into three categories: simple asphyxiants, irritant toxins, and chemical asphyxiants (Table 128–2). Simple asphyxiants, such as carbon dioxide, exert their toxicity by displacing oxygen, resulting in an oxygen-deprived environment.⁴⁶ To further complicate this issue, combustion consumes oxygen, further reducing the available oxygen in the environment (Chap. 124).⁴⁶

TABLE 128–2. Toxic Thermal Degradation Products

<i>Asphyxiants</i>	<i>Irritants</i>
Simple	High water solubility (upper airway injury)
Carbon dioxide	Ammonia
Chemical	Hydrogen chloride
Carbon monoxide	Sulfur dioxide
Hydrogen cyanide	Intermediate water solubility
Hydrogen sulfide	(upper and lower respiratory tract injury)
Oxides of nitrogen (methemoglobinemia)	Chlorine
	Isocyanates
	Low water solubility
	(pulmonary parenchymal injury)
	Oxides of nitrogen
	Phosgene

Irritant gases are chemically reactive compounds that exert a local effect on the respiratory tract, primarily through the production of acids, alkalis, or reactive oxygen species (ROS; Chap. 124). Ammonia is generated when wool, silk, nylon,

or synthetic resins are burned. It reacts with mucosal moisture to produce ammonium hydroxide.⁷⁸ Sulfur dioxide, an oxidation product of sulfur-containing material, is found in more than 50% of air samples from fires.²¹ Sulfurous acid forms when sulfur dioxide reacts with the water of the respiratory mucosa. Hydrogen chloride, chlorine, and phosgene are formed from the thermal degradation of polyvinyl chloride, a plastic widely used in home and office furnishings, floor coverings, and electrical insulation.^{14,15} In the presence of mucosal water, these combustion products generate hydrogen chloride and ROS.³⁴ Phosgene, which is also formed, typically reacts slowly, producing delayed alveolar injury.¹⁶ Isocyanates, generated from combustion of foam furniture padding, cause intense irritation of the upper and lower respiratory tracts.¹¹⁷ High concentrations of the irritant acrolein are measured in air samples from fire environments and in the blood of fire victims.¹⁴⁵ Acrolein penetrates cell membranes easily because it is lipid soluble and injures cells by denaturing cellular proteins.⁴⁷

Thermal degradation of organic material produces finely divided carbonaceous particulate matter (soot) suspended in hot air and gases. These particles are not just composed of carbon; organic acids, aldehydes, heavy metals, and reactive chemicals such as sulfur dioxide, hydrogen chloride, chlorine, and phosgene are adsorbed to their surface.^{72,121} Soot adheres to the mucosa of the airways, allowing adsorbed irritant xenobiotics to react with the mucosal surface moisture and often enhancing and prolonging exposure to irritants in a fire environment. The deposition of these particles in the respiratory tract depends on their size, with particles of 1 to 3 μm reaching the alveoli.⁹² Irritant gases can also “piggyback” on aerosol droplets and alter the site of gas deposition.⁵⁹ Experimental animals demonstrate markedly decreased lung injury when exposed to toxic gases from smoke that was filtered to remove particulates.⁷²

For irritant gases, the degree of water solubility is the most important chemical characteristic in determining the timing and anatomic location of respiratory tract injury. Highly water-soluble xenobiotics primarily injure the upper airway by rapidly combining with mucosal water, leaving little of the parent compound to travel further down the airway. These xenobiotics quickly damage mucosal cells, which subsequently release mediators of inflammation or ROS.^{19,80,94,121} This produces early irritation, providing a warning that the environment is unsafe and prompting escape. After more than a trivial exposure, the intense inflammatory response increases microvascular permeability and allows movement of fluid from the intravascular space into the tissues of the upper airway.⁹ The loosely attached underlying tissue of the supraglottic larynx may become markedly edematous, causing upper airway obstruction within minutes to hours.⁶⁵ The obstruction may progress to the point of complete upper airway occlusion.¹²⁸ Xenobiotics with low water solubility react with the upper respiratory mucosa more slowly and do not elicit the irritation or aversion stimulus that prompts an escape response. These xenobiotics more typically reach the distal lung parenchyma, where they react slowly to create delayed toxic effects. Xenobiotics with intermediate water solubility, such as chlorine, are more likely to result in damage to both the upper and lower respiratory tracts. Other factors, such as concentration of the inhaled xenobiotic, duration of exposure, particle size, respiratory rate, absence of protective reflexes, and preexisting disease influence the region of respiratory tract injury. For example, as the concentration of a highly water-soluble irritant gas increases more chemical is presented to the lower airway, possibly leading to damage of the lower respiratory tract. In addition, patients with loss of consciousness may increase their exposure secondary to their loss of protective reflexes.

Damage to the tracheobronchial tree is mediated by many of the same mechanisms as those of the pharynx and hypopharynx: inhaled particulates and toxic gases result in deposition of corrosives and oxidants. Direct thermal injury is less likely to occur as a result of the efficient cooling ability of the upper airways.⁹⁴ Direct injury to the tracheobronchial tree and an intense inflammatory response, evoked in part by airway nociceptive sensory neurons, leads to an increase in airway resistance from mucosal edema, bronchoconstriction, and accumulation of intraluminal debris and airway secretions.^{9,68,84,142} Increased tracheobronchial vascular permeability contributes to interstitial edema of the airways and increased airway resistance. Bronchoconstriction and subsequent wheezing are caused by a reflex response to toxic mucosal injury and a response to mediators of inflammation.^{55,143} Damaged cells release chemotactic factors that stimulate production of an exudate rich in protein, including fibrin and inflammatory cells.^{39,149} This injury eventually results in sloughing of the mucosa, which combines with inflammatory cells and exudate to create casts in the airways.³⁹ Casts can block both the small and large airways, increasing airway resistance and mechanically preventing passage of oxygen to the alveoli.³⁰

Irritant xenobiotics that reach the alveoli injure the lung parenchyma.¹⁰³ Corrosives, proteolytic enzymes, reactive free radicals, and mediators of inflammation all contribute to acute respiratory distress syndrome (ARDS).^{74,116,143,156} Pathophysiologic changes of ARDS decrease lung compliance, bacterial defenses, and lead to ventilation-perfusion mismatch with intrapulmonary shunting, increased extravascular lung water, and microvascular permeability.^{25,143,149,152} Lung compliance is further decreased by atelectasis when xenobiotics inactivate pulmonary surfactant.^{103,113} In animal studies, patchy atelectasis rapidly occurs after smoke inhalation.¹⁰³ In addition, ventilation-perfusion mismatch occurs when pulmonary blood flow is diverted by hypoxia and vasoactive mediators of inflammation.^{82,104} Xenobiotics cause additional injury by impairing mucociliary clearance, altering alveolar macrophage function, and impairing phagocytosis of bacteria, all of which predispose to pulmonary infections and sepsis.^{10,43,60,127} The combination of the delayed toxic effects

of some inhaled xenobiotics and the slowly developing inflammatory response may explain the limited initial manifestations of parenchymal injury during the first 24 hours after smoke exposure.

Nitric oxide plays a significant role in the pathogenesis of smoke inhalation induced lung injury.^{41,89,150} Combined smoke inhalation and burn injury results in an upregulation of inducible nitric oxide synthase (iNOS) mRNA synthesis in animal models and subsequently results in increased activity of iNOS.^{40,42,89,136} Increased concentrations of nitric oxide may result in myocardial contractile dysfunction with subsequent hypotension.¹³⁶ It also increases vascular permeability with resultant edema.⁸⁹ One possible mechanism is the formation of the highly reactive peroxynitrite (ONOO⁻) radical from the combination of nitric oxide and ROS, which may lead to alveolar capillary membrane damage and subsequent ARDS.^{40,89} Inhibition of iNOS reduced lung injury in combined smoke inhalation and burn injury in an ovine model.⁴¹

Chemical asphyxiants exert their toxic effects at extrapulmonary sites. Incomplete combustion of organic materials generates carbon monoxide, which is considered the most common serious acute hazard to victims of smoke inhalation injury ([Chap. 125](#)).^{1,145} Carbon monoxide (CO) prevents oxygen from binding to hemoglobin, creating a functional anemia. It also hinders the release of oxygen at the tissues, shifting the oxyhemoglobin dissociation curve to the left. In addition, CO binds myoglobin in cardiac and skeletal muscle and cytochrome oxidase in all tissues.^{23,66} The combination of these features impairs oxygen utilization by the myocardium and contributes to myocardial dysfunction. Other mechanisms of toxicity include induction of oxidative stress and lipid peroxidation ([Chap. 125](#)).¹⁴⁰

Cyanide is produced from combustion of organic nitrogen-containing products such as plastics, melamine resins, polyurethanes, wool, silk, nylon, nitrocellulose, polyacrylonitriles, synthetic nitrile rubber, and paper.¹¹² Many common building materials such as insulations and laminates are comprised of these cyanide-producing substances. High concentrations of cyanide are measured in air samples from fires, and elevated blood cyanide concentrations occur in both survivors as well as those who die in fires.⁴⁵ Cyanide has at least an additive, if not synergistic, effect with carbon monoxide in smoke inhalation toxicity ([Chaps. 125 and 126](#)).^{91,106,120} Combustion of nitrogen-containing materials also generates oxides of nitrogen, which are irritants and can induce the formation of methemoglobin ([Chap. 127](#)).

Depending on the fuel, other combustion products are aerosolized and act by local irritation or systemic toxicity. Metal oxides, hydrocarbons, hydrogen fluoride, and hydrogen bromide may contribute to toxicity. In addition, antimony, bromine, cadmium, chromium, cobalt, gold, iron, lead, and zinc often are recovered from air samples taken during fires and from soot removed from the surface of the trachea and bronchi of fire victims.^{11,33} Fires at industrial sites, clandestine drug laboratories, transportation incidents, and natural disasters, such as erupting volcanoes, produce additional unique toxic inhalants.

CLINICAL MANIFESTATIONS

The primary clinical problem in smoke inhalation victims is respiratory compromise; therefore, clinical evaluation should specifically address this issue. Patients may complain of mucous membrane, ocular, and pharyngeal irritation. Changes in voice may occur and speech may progressively worsen as the airway becomes increasingly edematous. Cough, chest tightness, and complaints of dyspnea are common. The patient may develop stridor and acute respiratory arrest. Patients may have difficulty managing their airway secretions, with expectoration of copious quantities of soot containing sputum.

On examination the patient may have burns to the face or singed hairs of the head, face, or nasal passages. The oropharynx and nares may be erythematous, coated with soot, or have progressive edema. Visualization of the vocal cords by laryngoscopy is sometimes difficult secondary to soot accumulation, secretions, or edema. Conjunctival injection, corneal ulcerations, marked lacrimation, and blepharospasm may be noted on ophthalmic examination.

Auscultation of the chest may reveal rhonchi, crackles, and wheezing suggestive of ARDS.⁵³ Bronchospasm may occur, particularly in patients with underlying reactive airway disease. Breath sounds, including wheezing, may become virtually inaudible in patients with severe bronchospasm. ARDS is a common complication and is defined as acute onset diffuse alveolar filling with hypoxemia not otherwise explained by congestive heart failure or fluid overload.¹⁴⁸ ARDS is classified as mild, moderate, or severe based on the degree of impairment as determined by the PO₂ to FiO₂ ratio ([Chap. 29](#)).¹⁴⁸

Tachycardia and tachypnea may be pronounced. Hypotension may occur, with faint or absent peripheral pulses.¹³⁶ Victims may develop altered mental status, including agitation, confusion, or coma. This is most often attributable to hypoxia from either pulmonary compromise or cellular hypoxia, but the altered consciousness may also be due to trauma, drug, or alcohol intoxication, or a combination thereof.

DIAGNOSTIC TESTING

Diagnostic studies should focus on assessing for airway and pulmonary injury as well as the ability of the patient to oxygenate and ventilate. An arterial blood gas (ABG) analysis with cooximetry and chest radiography (CXR) should be

obtained initially in all patients with smoke inhalation. Health care professionals should consider obtaining a rapid lactate concentration in all seriously ill patients to aid in evaluation of possible cyanide toxicity.

ABG analysis assesses both pulmonary function (gas exchange) and blood pH. The presence of metabolic acidosis may be an early clue to tissue hypoxia or cyanide poisoning. Serial measurements of arterial oxygenation and ventilation are helpful in identifying progressive hypoxemia or ventilatory failure. The accuracy of oxygen saturation measurement depends on the method used. Measurement of oxygen saturation by transcutaneous pulse oximetry is unreliable in patients with smoke inhalation because it overestimates oxygen saturation in the presence of carboxyhemoglobin.^{6,18,146} Similarly, oxygen saturation calculated from standard ABG analysis may be unreliable in the setting of an elevated blood carbon monoxide concentration. In the setting of smoke inhalation, oxygen saturation is most accurately determined by cooximetry which will directly measure oxygenated and deoxygenated hemoglobin.

Cooximetry also measures carboxyhemoglobin and methemoglobin concentrations and should be obtained for all victims of smoke inhalation.^{24,157} When using blood sampling, either arterial or venous samples can accurately measure carboxyhemoglobin concentrations.⁸³ Noninvasive bedside pulse cooximetry is a rapid and acceptably sensitive screening tool for the detection of carbon monoxide; its use is becoming more prevalent in clinical practice¹³⁰ (Chap. 29). Unfortunately, the carboxyhemoglobin concentration alone is a poor predictor of the severity of smoke inhalation because a low or nondetectable concentration does not exclude the possibility of developing inhalation injury.^{87,137} Rarely methemoglobin levels are elevated in fire victims. Because methemoglobin can further reduce oxygen-carrying capacity and contribute to morbidity, methemoglobin levels should also be included in the initial laboratory evaluation.^{62,133}

Blood cyanide analysis is of little clinical utility because results of analysis are not typically available for hours or days, and therapy should never await laboratory confirmation of the presence of cyanide. Accurate measurement depends on acquiring the sample soon after exposure as cyanide is rapidly eliminated from the blood.^{8,70} Blood pH and lactate are more useful tools in acutely assessing for cyanide exposure. A plasma lactate concentration greater than 10 $\mu\text{mol/L}$ in the setting of smoke inhalation suggests cyanide poisoning and supports empiric antidotal treatment of critically ill patients, particularly in the absence of an elevated carboxyhemoglobin level or shock.⁸

CXR should be obtained early in the assessment of a patient with smoke inhalation but is an insensitive indicator of pulmonary injury.^{118,153} In one series of patients admitted to the intensive care unit (ICU) with smoke inhalation, no significant differences in the duration of either ventilation or duration in the ICU stay were observed between those who exhibited abnormal findings on the first CXR examination and those without abnormalities.⁵³ The most frequent abnormal findings on initial CXR are diffuse alveolar and interstitial changes, found in up to 34% of patients.⁵³ Serial CXR after a baseline study are generally more helpful in detecting evolving pulmonary injury after smoke inhalation (Fig. 128–1).⁵⁵ Subtle findings within 24 hours of exposure include perivascular haziness, peribronchial cuffing, bronchial wall thickening, and subglottic edema.^{75,139} Widespread airway disease usually occurs more than 24 hours after inhalation injury and may represent ARDS, aspiration, infection, or volume overload.¹³⁹ Computed tomography (CT) of the lungs appears to be a more sensitive modality than plain radiography for detecting early pulmonary injury after smoke inhalation.^{71,115,125} However, no data are currently available to support improved patient outcomes when using this radiographic modality.

FIGURE 128–1. (A) Initial chest radiograph of a 3 year-old boy involved in a structural fire (approximately 60 minutes after the event). (B) Chest radiograph approximately 3 hours after exposure demonstrating the appearance of right upper lobe and perihilar infiltrates. (C) Evolution of chest radiograph findings approximately 17 hours after initial exposure demonstrating evolution of the right upper and perihilar infiltrates. (D) Approximately 60 hours after exposure demonstrating diffuse alveolar and interstitial infiltrates representative of inhalation induced acute respiratory distress syndrome. (Used with permission of The University of Virginia Medical Toxicology Fellowship Program.)

In intubated patients, diagnostic bronchoscopy may be useful in detecting those at risk for developing significant inhalational injury.¹³¹ Bronchoscopy allows for direct visualization and potential grading of the injury.^{2,95} While early bronchoscopy has yet to show an improvement in outcome, as therapeutic modalities designed to limit pulmonary damage continue to evolve, early predictors of inhalational injury, such as CT scanning and/or early bronchoscopy, may become more useful in identifying those patients who may benefit from such therapies.^{2,95,110}

MANAGEMENT

From oxygen acquisition to cellular utilization, the final common pathophysiologic effect from smoke injury is hypoxia. Basic critical care strategies that optimize oxygen delivery and utilization are of primary importance in treatment. Once removed from the source of exposure and placed on oxygen, the primary problems that the clinician must treat are the effects of thermal injury and irritant gases on the airway, and systemic effects of cellular asphyxiants. High-flow oxygen, preferably humidified, should accompany initial resuscitation in symptomatic patients. In hypotensive patients insert two large-bore intravenous (IV) lines and provide aggressive fluid resuscitation to optimize perfusion and aid in oxygen delivery.

Critical airway compromise may be present upon initial hospital presentation or may develop in the ensuing hours.^{54,128} A major pitfall in the management of smoke inhalation is failing to appreciate the possibility of rapid deterioration. History and physical findings help to determine significant thermal injury or smoke exposure and the potential for clinical deterioration. The clinical effects of smoke exposure and their appropriate treatment are described in [Fig. 128–2](#). Early airway intervention must always be considered as a seemingly patent airway may develop progressive obstruction that can make subsequent intubation difficult or impossible. For signs of current or impending airway compromise, upper airway patency must be rapidly established. When obvious oropharyngeal burns are observed, upper airway injury almost certainly is present. Singed hairs of the head, face, or nasal passages and soot in the oropharynx or nares may signify potential for airway edema.

FIGURE 128–2. The final common pathway from all pathophysiologic changes that occur in smoke inhalation is hypoxia. All treatments should be focused on improving oxygen delivery and oxygen utilization.

Even if overt injuries are not visualized, distal injury may be present and underestimated.⁵⁴ Direct evaluation of the upper airway, preferably with fiberoptic endoscopy, is essential for assessing patients at high risk for inhalation airway injury.^{54,55,65} When evidence of upper airway injury exists, early endotracheal intubation should be performed under controlled circumstances, preferably with preparations for advanced or surgical airway interventions in the event that orotracheal intubation cannot be easily established. Other indications for early intubation include coma, stridor, and full-

thickness circumferential neck burns.^{7,54,55,128} Edema of injured tissue, including that of the airway, is worsened with massive fluid resuscitation in burned patients; therefore, health care professionals should also consider early intubation for patients with any amount of inhalation injury and concomitant dermal burns undergoing aggressive fluid management.^{54,55,98,128}

Pathophysiologic changes in the lung may result in progressive hypoxia over hours to days. Basic treatment of progressive respiratory failure includes continuous positive airway pressure, mechanical ventilation using lung protective strategies, positive end-expiratory pressure (PEEP), and vigorous clearing of pulmonary secretions.¹⁰¹ Decreased lung compliance is common secondary to cast formation, tissue damage, and atelectasis.^{90,101} Recommendations for limiting barotrauma in mechanically ventilated patients include using a low tidal volume (6–8 mL/kg), PEEP, and allowing permissive hypercapnia as necessary.^{81,90,100} Fraction of inspired oxygen (FiO₂) should be weaned to below 0.4 as rapidly as tolerated to limit oxygen toxicity.⁹⁰ Frequent airway suctioning, chest physiotherapy, and therapeutic bronchoscopy can clear inspissated secretions, plugs, and casts.^{30,90,97} As xenobiotics and soot can coat the airway in smoke inhalation victims, early bronchoscopy with bronchoalveolar lavage would intuitively be logical in an attempt to decontaminate the airway, similar to irrigation for dermal exposure. However, there are no data available regarding this modality in the care of smoke inhalation. High-frequency percussive ventilation (HFPV) may be considered as an alternative to conventional forms of ventilation in patients with inhalational injury. Several studies have investigated the use of HFPV in ventilated patients with inhalational injury. Although limited, some evidence suggests that HFPV may decrease peak pulmonary pressures, limit barotrauma, decrease the incidence of pneumonia, and improve mortality.^{22,28,50,90,124} A number of studies have examined experimental therapies such as percutaneous arteriovenous carbon dioxide removal, perfluorocarbons, inhaled nitric oxide, extracorporeal membrane oxygenation, instillation of natural surfactant into the lung, and deferoxamine–hetastarch complex for improving inhalation injury; however, none of these modalities have been definitively shown to improve outcome.^{29,35,57,73,96,105,108,109,122}

Inhaled β_2 -adrenergic agonists are considered first-line therapy for acute reversible bronchoconstriction resulting from asthma or chronic obstructive pulmonary disease and can be used to improve oxygenation and ventilation in victims of smoke inhalation. Pathophysiologic changes induced by irritant toxins in smoke are similar to those found in asthma, suggesting that β_2 -adrenergic agonists would also improve airflow obstruction in smoke inhalation.^{69,86} β_2 -adrenergic agonists also possess antiinflammatory properties, partially through interaction with β -adrenergic receptors on immune cells.^{85,151} β_2 -adrenergic agonists may also enhance resolution of alveolar edema by modulating the flow of sodium and potassium across cell membranes.^{85,151} Limited data in an ovine model suggest that nebulized albuterol may improve pulmonary function after smoke inhalation and burn injury.¹¹⁴ Although human data on the efficacy of β_2 -adrenergic agonists in smoke inhalation injury are lacking, their role is well established in conditions with reversible bronchoconstriction; animal studies lend support for their use and the potential benefits greatly outweigh the risks.^{114,151}

Corticosteroids have been used for smoke inhalation in an attempt to limit inflammation and improve outcome. One argument for their use is for the treatment of lung injury induced by oxides of nitrogen. Pulmonary sequelae, including bronchiolitis obliterans, are known to occur after significant exposure to oxides of nitrogen, which may be a prominent composition of smoke.^{64,76} Although data regarding efficacy are limited, corticosteroids are often used in treatment of nitrogen oxide exposure in relation to industrial exposure and silo filler's disease to prevent bronchiolitis obliterans.^{64,134} The mixed xenobiotic exposure from smoke inhalation appears to further complicate the outcome. One early rat study showed a trend toward reduced mortality in animals given supraphysiologic doses (25–100 mg/kg) of methylprednisolone; however, other tested corticosteroids (hydrocortisone, dexamethasone, cortisone) failed to demonstrate similar improvement. Consequently, this study failed to effectively prove that corticosteroids reduce mortality after rat exposure to white pine smoke.³⁸ Human studies have also failed to show an improvement in clinical outcome and may trend toward worsening outcome.^{20,77,102,129} Thus, the available literature does not support the use of corticosteroids for treatment of patients with smoke inhalation.

A significant amount of pulmonary injury after smoke inhalation is attributable to free radical damage. Smoke inhalation decreases systemic concentrations of the antioxidant vitamin E in sheep models and treatment with nebulized vitamin E (α - and γ -tocopherol) attenuates smoke inhalation induced pulmonary injury in animal models.^{51,93,144,155} Similarly, both nebulized heparin and N-acetylcysteine (NAC) are used by some centers to limit pulmonary damage.⁸⁸ Heparin is a glycosaminoglycan with anticoagulant and antiinflammatory properties occasionally used both topically and intravenously in burn treatment. In an ovine model of combined cutaneous burn and smoke inhalation, nebulized heparin combined with recombinant human antithrombin reduced airway obstruction and improved gas exchange.³⁹ The mechanism is likely attributable to decreased airway inflammation and decreased fibrin deposition and, consequently, decreased cast formation in the airway.³⁹ Nebulized heparin combined with NAC appeared to attenuate lung injury in two small studies; however, other studies have failed to show benefit.^{37,63,88} Human data are currently limited regarding each of these modalities with little current evidence that each treatment improves outcomes. The initial treatment strategy for carbon monoxide poisoning

focuses on optimizing oxygen delivery with supplemental oxygen administration.

Oxygen can be administered by a high-flow tight-fitting mask, endotracheal tube, or hyperbaric oxygen therapy (HBO). HBO can achieve very high arterial oxygen concentrations enhancing oxygen delivery to tissues and accelerating elimination of carbon monoxide from blood and tissues.^{56,119} HBO is recommended as a modality for treatment in certain situations involving carbon monoxide exposure; however, smoke inhalation injury is much more complex than poisoning with carbon monoxide alone (eg, a furnace leak).⁵² In victims of smoke inhalation, other clinical requirements, such as maintaining a secure airway and the need for additional resuscitative measures to treat ARDS, cardiovascular instability and metabolic derangements go beyond providing supplemental oxygen to treat CO poisoning. Optimal timing of HBO administration is often during the same period when intensive resuscitative efforts and focused ventilator management are required and could limit attention to these important therapies. In addition, it is known that pulmonary toxicity may result from elevated partial pressures of oxygen.¹³⁵ Very little information is available to predict the effect of hyperoxygenation on pulmonary toxicity following smoke inhalation.^{141,154} Therefore, the decision to treat a smoke inhalation patient with HBO should take into account risks and other clinical requirements when determining the appropriate therapy¹⁷ (Chap. 125 and Antidotes in Depth: A37).

Cyanide is a common product of combustion, with toxic concentrations often measured in fire victims. Because no diagnostic test is readily available in the field or in the emergency department, cyanide poisoning should be suspected in seriously ill patients with smoke inhalation, particularly in the presence of metabolic acidosis with an elevated lactate concentration.^{44,126} Serum lactate concentrations at the time of hospital admission correlate closely with blood cyanide concentrations, with serum lactate concentrations of 10 $\mu\text{mol/L}$ reported to be a sensitive indicator of cyanide toxicity.⁸ Baud demonstrated that carboxyhemoglobin levels of more than 10% also correlate with elevated cyanide concentrations. Additional clinical markers of potential cyanide poisoning include alteration of the central nervous system and cardiac function, although other factors of smoke inhalation injury can have similar effects. Specific treatment of cyanide toxicity should be implemented while other life support measures, including 100% oxygen therapy, are instituted.^{8,91,107} Treatment options include supportive care with or without empiric administration of a cyanide antidote. Systematic reviews of the human evidence regarding various cyanide antidotes conclude that it is possible to survive even cardiorespiratory arrest due to cyanide poisoning if given an appropriate antidote.^{48,123} In one review, 50% of cyanide poisoned victims (the majority due to smoke inhalation) had transient return of spontaneous circulation and 12% survived to hospital discharge; outcomes of treatment with hydroxocobalamin, thiosulfate, or a combination of sodium nitrite, amyl nitrite, and sodium thiosulfate were indistinguishable.^{48,123} The reviews found the onset of action of sodium thiosulfate slower when compared to hydroxocobalamin as the only clinically significant difference.^{48,123} Because definitive evidence of superiority is lacking, hydroxocobalamin (with or without sodium thiosulfate as an adjunct) or sodium thiosulfate alone are the antidotes of choice and should be considered for administration to smoke inhalation victims suspected of cyanide poisoning and exhibiting neurological impairment, cardiorespiratory collapse, or metabolic acidosis with elevated lactate¹²³ (Chap. 126, Antidotes in Depth: A38 and A40).

Cyanide antidotes are intended as an adjunct to basic critical care strategies that optimize oxygen delivery and utilization. Therefore, the amyl nitrite and sodium nitrite components of the classic cyanide antidote kit should be avoided in victims of smoke inhalation. Amyl nitrite and sodium nitrite produce methemoglobinemia, which binds cyanide to form cyanmethemoglobin (Chap. 126 and Antidotes in Depth: A38). Unfortunately, methemoglobin is a dysfunctional type of hemoglobin that poorly utilizes oxygen, impairing delivery to the tissues.³¹ Impairing oxygen-carrying capacity and oxygen delivery to tissues with nitrite-induced methemoglobinemia is a valid concern in the presence of tissue hypoxia from carboxyhemoglobinemia, lung injury, or other factors. Furthermore, rapid infusion of sodium nitrite may cause hypotension secondary to vasodilation.⁴⁹

Victims of fires may have respiratory compromise and other pathology not directly related to smoke inhalation, but rather from trauma or other underlying medical problems. Trauma from falls or explosions must be suspected and treatment started simultaneously with treatment of burns and inhalation injury. Comatose patients should be considered to have other causes for their status and should receive naloxone, thiamine, and hypertonic dextrose as indicated. Inhaled xenobiotics, such as carbon monoxide, may directly cause altered mental status, but drug and ethanol intoxication contribute significantly to fire fatalities and injuries. Blood ethanol concentrations correlate with elevated concentrations of carbon monoxide and cyanide, implying that intoxication impairs escape and prolongs toxic smoke exposure.^{5,11,99} Intracranial pathology should be considered and CT scans obtained as indicated.

Xenobiotics may injure the skin or mucous membranes in addition to the respiratory mucosa.²⁷ The duration of contact of a xenobiotic with tissue is an important factor in determining the extent of chemical injury to the skin and eyes. Rapid removal of soot from the skin or eyes may prevent continued injury. The eyes should be evaluated for corneal burns caused by thermal or irritant chemical injury. Patients with signs of ophthalmic irritation should have their eyes irrigated, and dermal decontamination should be considered to prevent burns from toxin-laden soot adherent to the skin.

SUMMARY

- Smoke inhalation contributes significantly to the morbidity and mortality of fire victims.
- Smoke inhalation is a complex syndrome involving diverse toxicologic injury. A spectrum of damage may occur, ranging from rapid upper airway occlusion to delayed ARDS.
- The end result of toxicity is tissue hypoxia.
- Goals of treatment should focus on maximizing oxygen delivery while avoiding unnecessary therapies that may hinder oxygenation.
- Early airway management should be implemented for patients with airway compromise. High-flow oxygen will help reverse tissue hypoxia, and fluid resuscitation should be instituted to improve cardiovascular status.
- Definitive antidotes are available in select cases and should be utilized when appropriate to help stabilize the patient.

129 NANOTOXICOLOGY

Silas W. Smith

HISTORY

Nanotechnology has been serendipitously employed by humanity for hundreds of years. Artistically, gold-ruby glass (cranberry glass), present in the Roman Lycurgus cup and later in many church stained glass windows, owes its striking red color and optical properties to gold nanoparticles created when a gold precursor is added to molten silicate glass.¹²² Cosmetically, to blacken hair, the Greco-Roman practice of mixing of lead oxide and slaked lime with water created lead sulfite nanocrystals (5 nm), which accumulated in the hair cuticle and cortex.³⁷¹ Martiallly, seventeenth century Damascus steel sword blades owed their high-quality mechanical properties to carbon nanotubes (CNTs) and cementite (Fe_3C) nanowires found within their structure.²⁸⁹ Medicinally, specially prepared, “Swarna bhasma,” nanosized colloidal gold, has been employed as an antirheumatic, anti-asthmatic, and anti-diabetic in Indian Ayurvedic practice for centuries.³⁷

Langmuir’s detailed experimental work establishing the existence of monatomic films garnered him the Nobel Prize in 1932.¹⁷² In 1959, the physicist Richard Feynman proposed the theoretical framework for “manipulating and controlling things” all the way down to the atomic level.⁸⁹ Norio Taniguchi is generally credited with coining the term “nanotechnology”—“the processing of separation, consolidation and deformation of materials by one atom or one molecule”—in 1974.³⁴⁰ The invention of the scanning tunneling microscope in 1981 enabled the visualization of individual atoms and allowed the direct physical manipulation of atomic surfaces.¹⁵² In 1985, Kroto and colleagues reported on a novel, minute crystalline allotropic form of carbon, conceptualized some 15 years previously.^{57,166,258} These soccer ball-shaped carbon-60 structures were named “buckminsterfullerenes” after Buckminster Fuller. The discovery of CNTs followed in 1991.¹³⁴

Health and safety of nanotoxicology came to fore during the first consumer recall of a purported nano-based invention.³⁸⁴ In 2006, the bathroom cleaning product “Magic-Nano” was released in Germany. Within days, more than 110 cases of illness were reported, and several patients were hospitalized with severe respiratory complaints, including acute lung injury. No further episodes of illness occurred after product recall only 3 days after introduction.¹⁴⁷ Although it was ultimately determined that “Magic-Nano” contained no nanoparticles, the incident raised many questions about nanotechnology development, regulation, and health risks.^{21,22} More than 1600 consumer products now incorporate nanotechnology, with multiple products reaching the market weekly.³⁴⁶

PHYSIOCHEMICAL PRINCIPLES

Nanotechnology is defined as the “control and restructuring of matter at the nanoscale, in the size range of approximately 1 to 100 nanometers, in order to create materials, devices, and systems with fundamentally new properties and functions due to their small structure.”²⁸¹ The American Society for Testing and Materials (ASTM) International defines an ultrafine particle as a particle ranging in size from approximately 0.001 (1 nm; 10 Å) to 0.1 μm (100 nm; 1000 Å) and a nanoparticle as an ultrafine particle with lengths in two or three dimensions greater than 0.001 μm (1 nm; 10 Å) and smaller than about 0.1 μm (100 nm; 1000 Å).⁸

For spherical nanoparticles, as particle diameter decreases, the percentage of molecules on the surface of the nanoparticle increases relative to the total number of molecules. This percentage increases quite steeply below 100 nm.¹⁶³ This provides a large area (high surface to volume ratio) for chemical reactions to occur and for contact and interaction with biologic systems. Furthermore, as particles reach sizes below 100 nm, quantum mechanical principles become manifest, and, thus, acoustic, diffusion, electrical, magnetic, mechanical, optical, and solubility properties may emerge, which differ from those seen at larger as well as smaller (atomic) scales. Nanoparticles may exist as aggregations (individual particles held together by strong forces) and agglomerations (held together by weak forces such as van der Waals forces, electrostatic, and surface tension). The extent of aggregations and agglomerations, particle dispersal, and electrical charge varies, depending on the primary particle constituents and on solvents or media.³³ This imparts additional properties to identical substances even at the nanoparticle level. Whereas C_{60} fullerenes are intensely hydrophobic and essentially insoluble in water, colloidal C_{60} clusters remain mono-dispersed in water as long as electrostatic repulsions are

not disrupted by salts.³³ Single elemental materials can also be engineered with complex architecture (eg, gold and platinum nanostars) to alter catalytic activity.²⁰⁰

Nanoparticles may be derived “naturally,” such as those originating from volcanic explosions, fires, ocean spray, sand storms, soil and sediment weathering, and biomineralization processes.³⁶¹ “Incidental” nanosized particles are generated as byproducts of processes such as combustion, cooking, or welding, or even simply rubbing bulk solids of C_{60} between fingertips or glass slides.⁶³ “Engineered” nanomaterials are intentionally created for research purposes or for manufacture for end-use applications. Nanomaterials and nanoparticles include a vast array of structures, such as coatings, composite nanodevices, dendrimers, fullerenes, graphenes, liposomes, nanocrystals, nanogels, nanofibers (nanotubes and nanorods), nanoshells, nanospheres, nanowires, polymeric micelles, quantum dots (QDs) and quantum rods, and supermagnetic particles (Fig. 129–1). They are composed of materials as diverse as their applications, including carbon, lipids, metals and metal oxides (eg, cadmium, cerium, copper, germanium, gold, iron, silver, selenium, zinc, zirconium), nucleic acids, polymers, proteins, and combinations thereof.

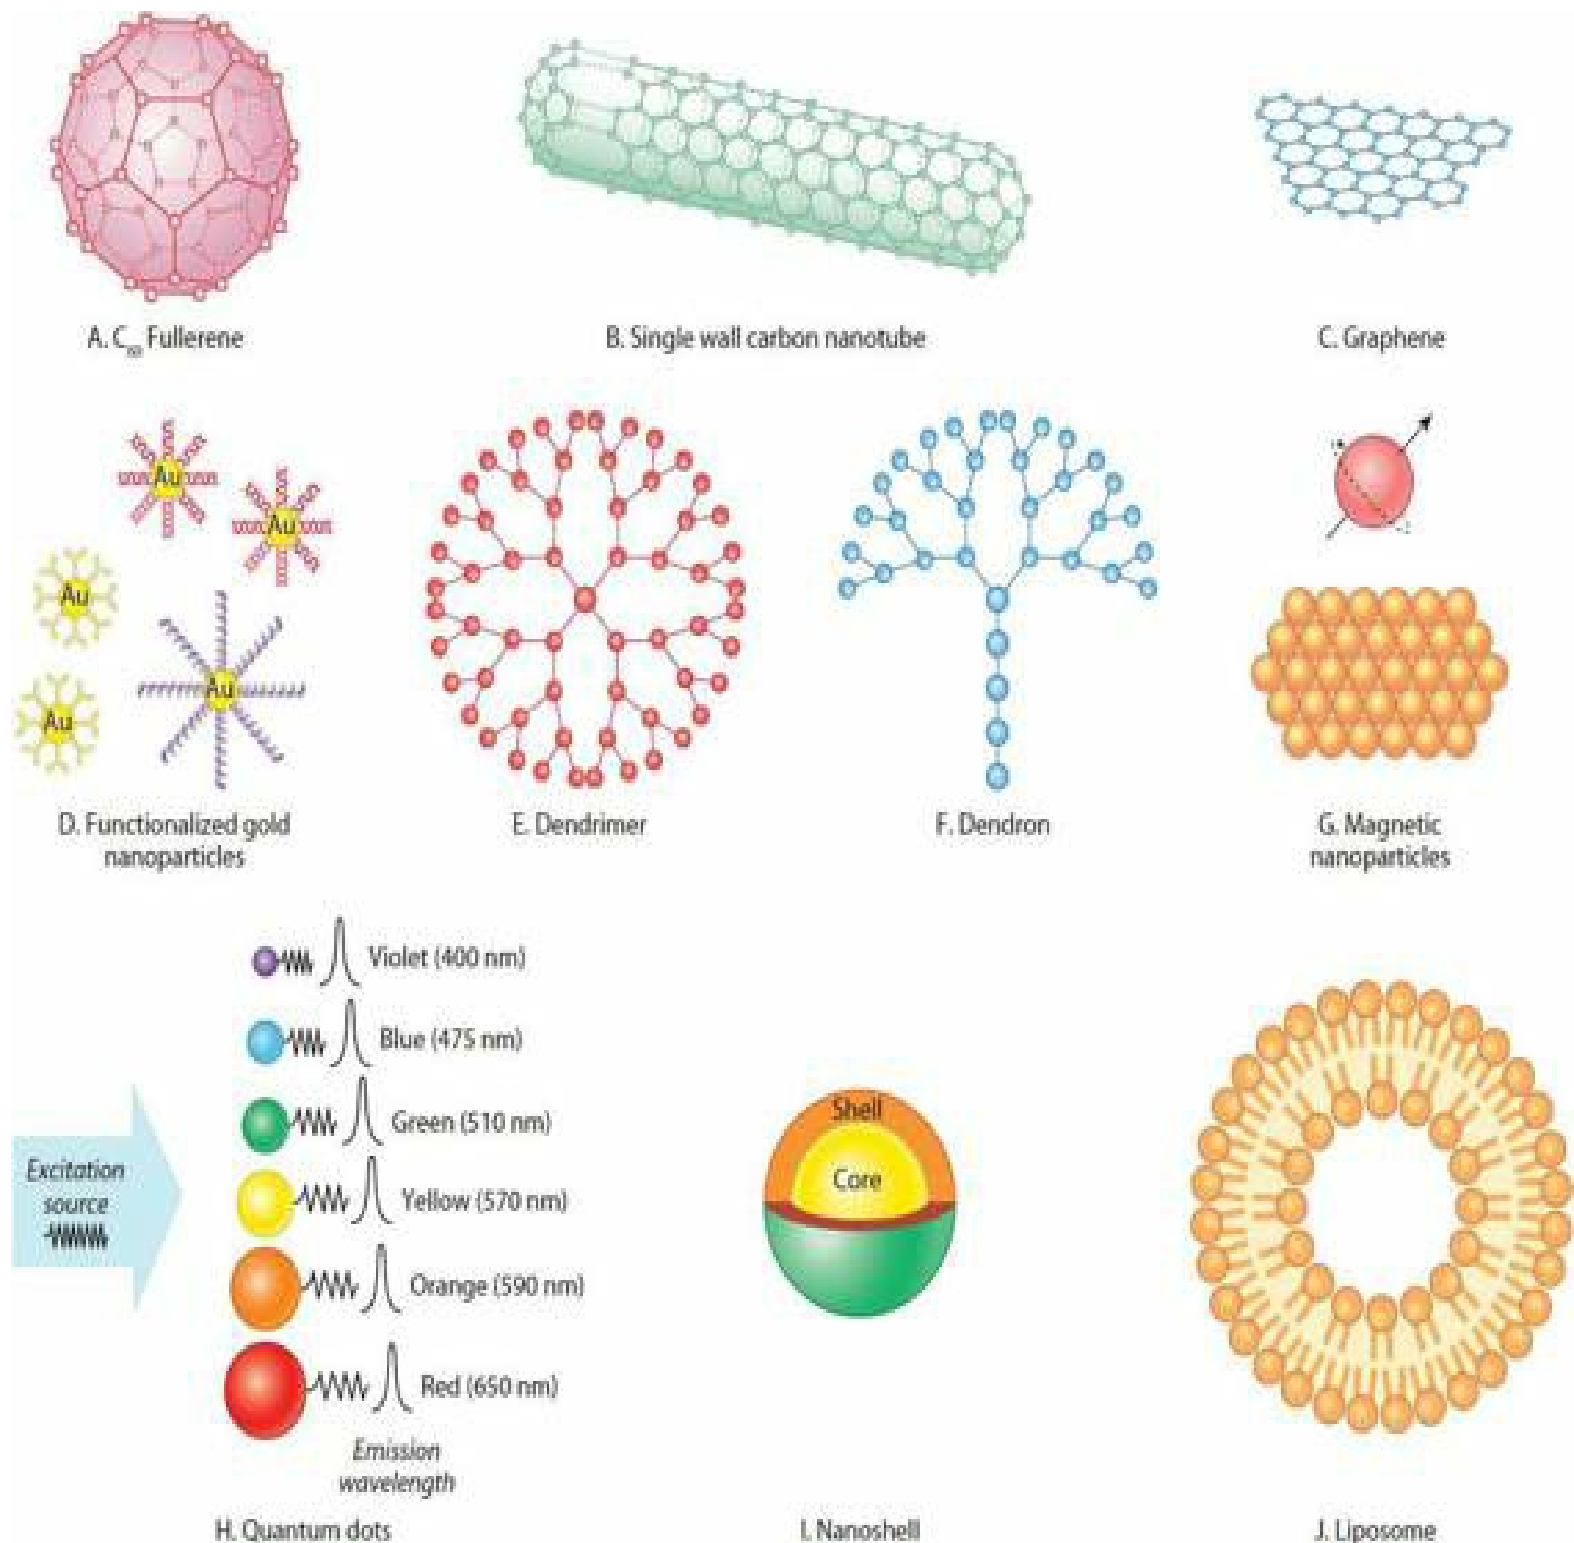

FIGURE 129–1. Nanoparticles (not to scale). (A) C_{60} is a prototypical fullerene, or carbon cage, which may enclose additional atoms, ions, or molecular clusters. Fullerols (fullerenols) employ polyhydroxylation at their surface to improve water solubility. (B) Carbon nanotubes (CNTs) are single-walled (SWCNTs) or multiple-walled (MWCNTs) cylinders,

which are capped at each end and can bundle together into longer and wider agglomerates. (C) Graphene consists of a single layer of carbon atoms (ie, a sheet) in a hexagonal lattice. (D) Gold nanoparticles and other nanosized noble metals (eg, silver, copper, platinum) have unusual catalytic, optical, electronic, and (photo)thermal properties and can be conjugated to dyes, antibodies, peptides, and oligonucleotides. (E) Dendrimers are branched polymers consisting of a central core, an internal branching region, and surface terminal groups; drugs, genes, and imaging agents can be loaded into the inner protected cavities. (F) Dendrons are wedge-shaped sections of dendrimers with an accessible reactive group. (G) Magnetic nanoparticles include superparamagnetic iron oxide (SPIO) nanoparticles (Fe_2O_3 , Fe_3O_4), pure metals (Fe and Co), and alloys (CoPt_3 and FePt). They are usually surrounded by a shell to minimize agglomeration and chemical reactivity. Magnetism-engineered iron oxide (MEIO) nanoparticles can be doped with cobalt, manganese, and nickel to create unique magnetism properties. (H) Quantum dots (QDs) and QRods (rod-shaped QDs) are semiconductor nanocrystals capable of size-dependent fluorescence with a “tunable” emission spectrum in the 400-nm to 2- μm range. Analogous but chemically inert Cornell dots (CU or C dots) contain covalently bound fluorescent dyes in a sol–gel-derived silica matrix. (I) Nanoshells contain a dielectric silica core surrounded by thin metal gold shell. (J) Liposomes are globular vesicles with hydrophobic and hydrophilic zones composed of phospholipids, sphingolipids, and ceramides or other esters or polymers ranging in size from 25 nm to the micron range. Nanoparticles can be further derivatized, chemically modified, or bioengineered with a variety of detection, imaging, or targeting molecules.

CURRENT AND PROJECTED APPLICATIONS

Nanotechnologies are currently or anticipated to be incorporated into an ever-widening range of disciplines and industries. These include agriculture; automobile components; chemical and materials science (alloys, catalysts, ceramics, coatings, and thin films), defense, electronics, energy capture and storage, environmental sensing and remediation, food processing, fuel additives, house-cleaning products, paints, flame-retardants, varnishes, and sealants, pharmaceuticals, textiles, and water purification.²⁸¹ Specific human and biomedical applications include biomaterials, cosmetic and external products, diagnostics, drug and gene delivery systems, imaging, immune and transplantation sciences, and oncology therapy.³⁰⁶ Biomaterial products include creation of scaffolds for in vivo or ex vivo growth to support tissue healing, engineering, and regenerative medicine; coatings to minimize immunogenicity, inhibit specific tissues or cell types, and allow macromolecular repair; and implant engineering in prosthetics to control fibrous tissue formation and biointegration, and implant performance.^{93,336,344,345} Nanotechnology is radically advancing imaging capability for specific organs, tumors, sentinel lymph nodes, and vasculature. Molecular imaging now permits differentiation of cellular subcompartments, uptake mechanisms, cell architecture, intracellular trafficking, and single proteins and receptors.^{14,108,167} Sunscreens, cosmetics, and conditioners have embraced a range of nanotechnologies. Nanoformulations of TiO_2 and ZnO , which the FDA has permitted in sunscreens since 1999, provide both aesthetic appeal (sunscreen with transparency, lower viscosity, and improved skin blending) and clinical benefit (more efficient UV filtration).^{244,384} Wound care is incorporating dressings containing nanocrystalline silver and other delivery systems in order to improve wound healing through inflammation suppression, upregulation of micronutrients, and antibacterial actions.^{232,349,376} Nanotechnology is advancing medical diagnostic capability, detection thresholds, and pathogen sensing, with tagged nanoparticles currently employed in commercial genotyping tests and other assays.³³³ Nanoengineering holds the promise of improved pharmacokinetics, solubility, delivery, and targeting of pharmaceuticals, proteins, and genes in a cell-, tissue-, tumor-, or organ-specific manner. New formulations, magnetic drug targeting, thermal ablation, and delivery to incredibly diverse difficult-to-access spaces (eg, intracellular pathogens, tumors, and the central nervous system) are being investigated or brought to market.^{23,154,313,319,377} Table 129–1 presents selected commercial nanotechnology-based diagnostics, imaging compounds, and therapeutics.

TABLE 129–1. Selected Commercial Nanotechnology-Based Diagnostics and Therapeutics

<i>Xenobiotic</i>	<i>Proprietary Name</i>	<i>Route</i>	<i>Class or Indication</i>	<i>Nanotechnology Platform</i>
Aminosilane/iron oxide	NanoTherm (EU)	IV	Magnetic tumor thermotherapy	SPIO nanoparticle (aminosilane-coated)
Amphotericin	Abelcet, Amphotec, Ambisome	IV	Antifungal	Liposomal
Aprepitant	Emend	PO	Antiemetic	Nanocrystal
Certolizumab pegol (TNF antagonist)	Cimzia	SQ	Immunosuppressant	Polymer-protein conjugate
Cytarabine	Depocyt	IV	Chemotherapeutic	Liposomal
Daunorubicin	DaunoXome	IV	Chemotherapeutic	Liposomal
Dendoleukin diltiox	Ontak	IV	Chemotherapeutic	Diphtheria toxin-antibody-functionalized nanoparticle
Dominant-negative construct of human cyclin-G1 gene	Rexin-G ⁺ (Philippines)	IV	Chemotherapeutic	Targeted (collagen binding domain) nanoparticle
Doxorubicin	Doxil, Caelyx, Myocet	IV	Chemotherapeutic	Liposomal
Estradiol	Estrasorb	TD	Menopausal symptom	Micellar nanoparticle
Estradiol	Elestrin	TD	Menopausal symptom	Calcium phosphate nanoparticles
Fenofibrate	Tricor, Triglide	PO	Antilipidemic	Nanocrystal
Ferucarbotran	Resovist (EU)	IV	MRI contrast agent	SPIO nanoparticle (carboxydextran-coated)
Ferumoxide	Feridex, Endorem	IV	MRI contrast agent	SPIO nanoparticle (dextran-coated)
Ferumoxil	GastroMARK, Lumirem	IV	MRI contrast agent	SPIO nanoparticle (siloxane-coated)
Glatiramer acetate (L-glutamic acid polymer with L-alanine, L-lysine and L-tyrosine)	Copaxone	SQ	Autoimmune disease mitigation (multiple sclerosis)	Polymeric substances
Gold	Verigene	NA	Molecular diagnostics	Oligonucleotide- or antibody-functionalized nanoparticle

Peginesatide (erythropoietin receptor agonist)	Omontys ^d	IV, SQ	Polycythemic	Polymer protein conjugate
Peginterferon alfa-2b	PegIntron	SQ	Antiviral (hepatitis C)	Polymer protein conjugate
Peginterferon alfa-2b	Pegasys	SQ	Antiviral (hepatitis B/C)	Polymer protein conjugate
Pegloticase	Krystexa	IV	Antihyperuricemic	Polymer protein conjugate
Pegvisomant (PEG-human growth hormone analog)	Somavert	SQ	Acromegaly	Polymer protein conjugate
Propofol	Diprivan	IV	Anesthetic	Liposome
Sevelamer HCl (crosslinked with epichlorohydrin)	Renagel	PO	Phosphate reduction	Polymeric crosslinked resin
Silver	Acticoat	Topical	Wound healing	Nanoparticle
Sirolimus	Rapamune	PO	Immunosuppressant	Nanocrystal
Titanium dioxide	Numerous	Topical	Ultraviolet-protectant	Nanoparticle
Vincristin	Marqibo	IV	Chemotherapeutic	Liposomal
Verteporfin	Visudyne	IV	Aged-related macular degeneration	Liposomal

^aUS FDA Orphan Drug Approval but not Marketing Approval. ^bSouth Korean marketing approval. ^cUS FDA IND approval. ^dVoluntary marketing withdrawal.

EU = European Union; G-CSF = granulocyte-colony stimulating factor; GM-CSF = granulocyte-macrophage colony stimulating factor; IND = investigational new drug; IM = intramuscular; IV = intravenous; I/O = intravitreal; MRI = magnetic resonance imaging; NA = not applicable; PEG = polyethylene glycol; PO = oral; SCID = severe combined immunodeficiency disease; SPIO = superparamagnetic iron oxide; SQ = subcutaneous; TD = transdermal; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor; NA = not available. No endorsement is implied.

EXPOSURE AND DISTRIBUTION

Nanoparticle exposure is anticipated through a variety of mechanisms (Fig. 129–2). Exposure might occur through environmental discharge into air, water, or soil during the primary manufacturing process; disposition of industrial or research waste; or engine combustion. Sanding, machining, wearing and weathering, or disposing of nanomaterial-containing products could also liberate nanoparticles. Exposure might also occur during biologic elimination from a primary target or due to implant or device wear.

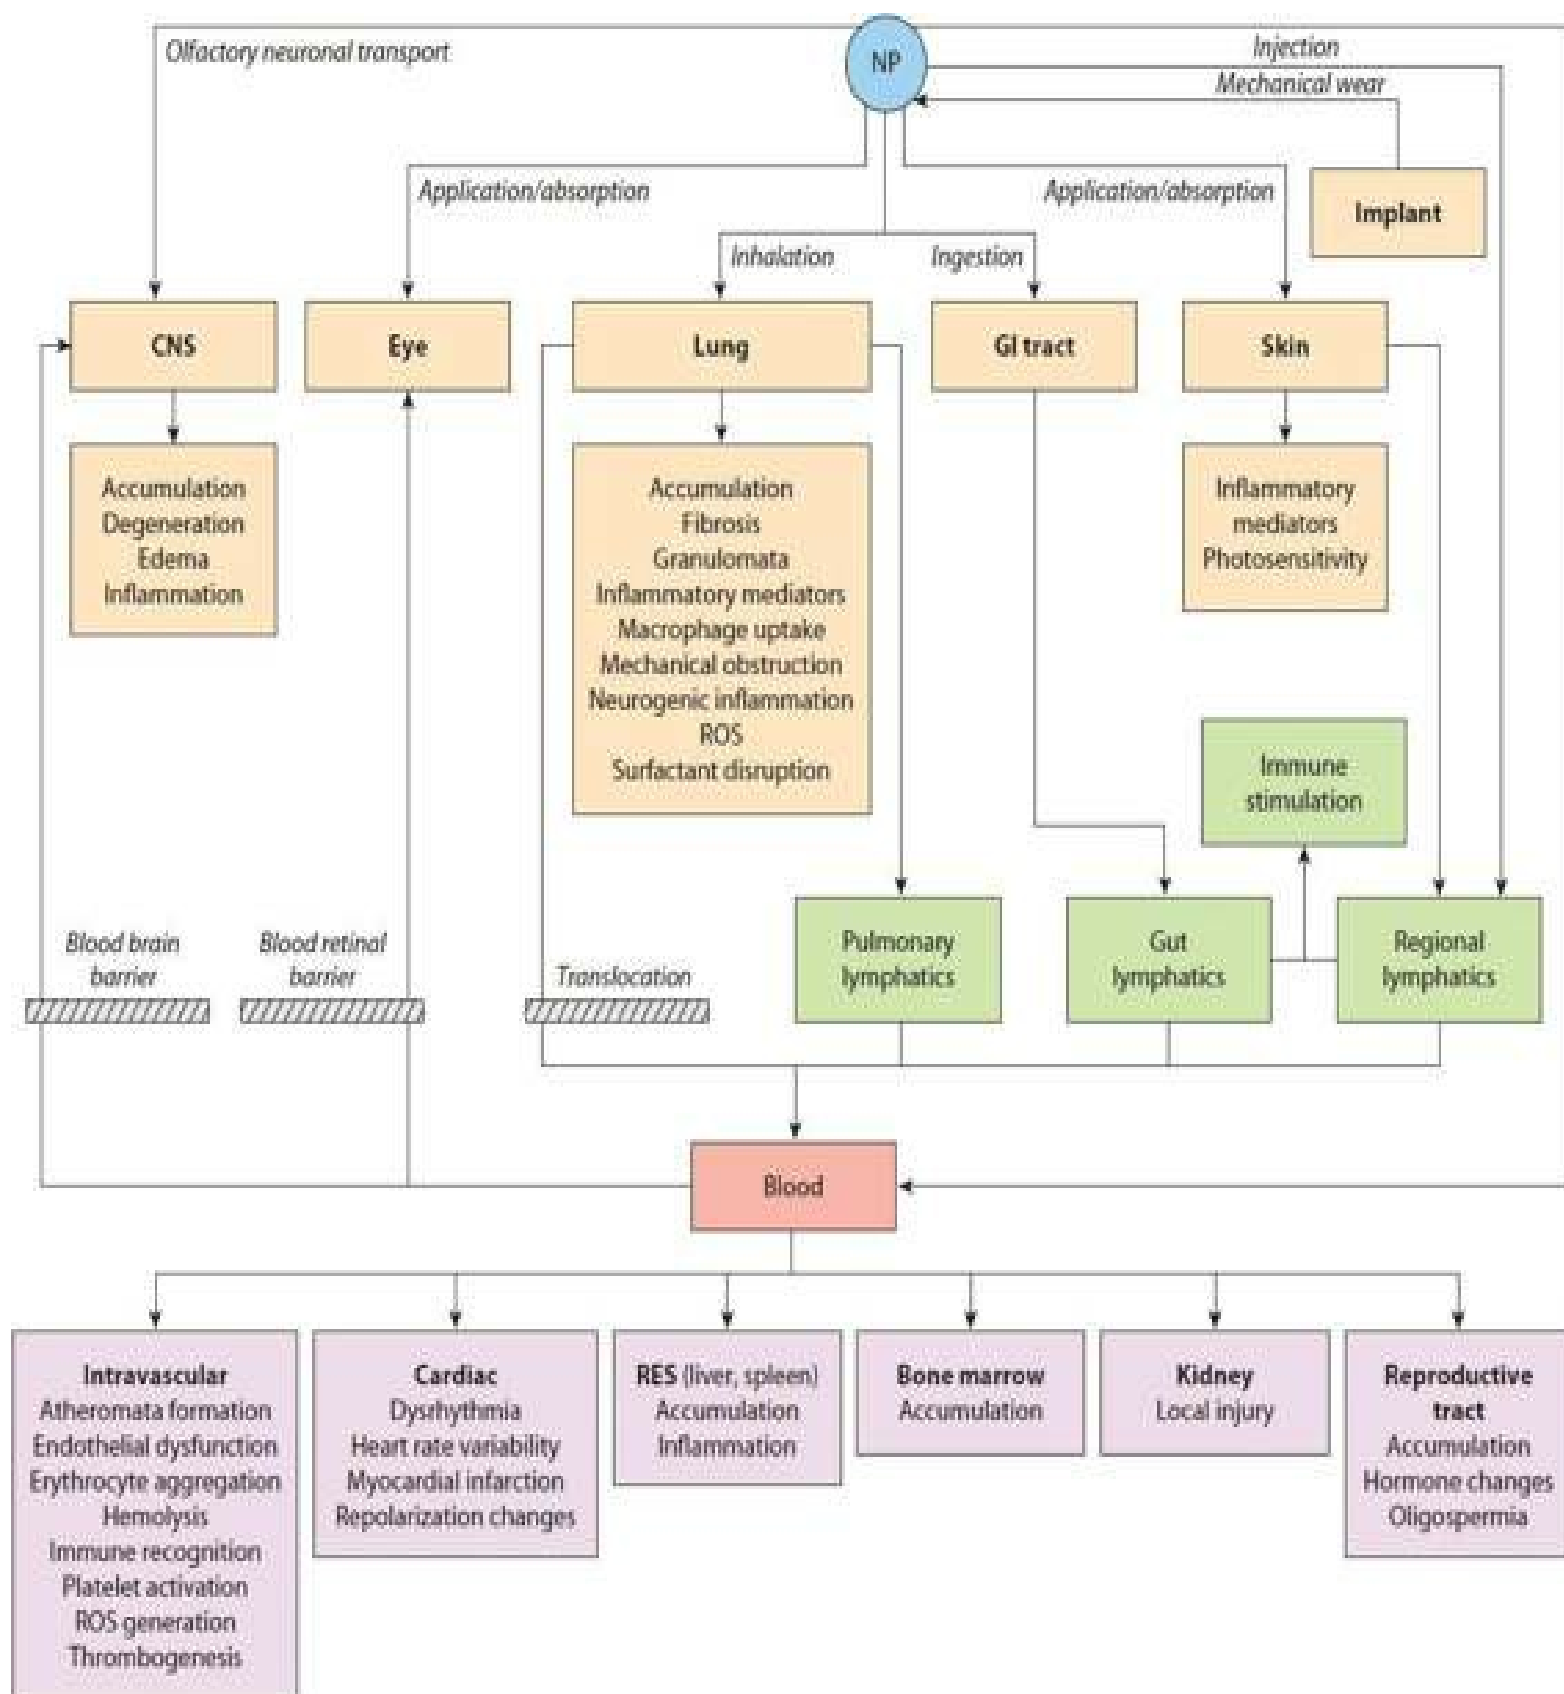

FIGURE 129–2. Potential mechanisms of nanoparticle exposure, distribution, and systemic toxicity. Accumulation may not be limited to the organ systems depicted. NP = nanoparticle; RES = reticuloendothelial system; ROS = reactive oxygen species.

Dermal Exposure

Podoconiosis (endemic non-filarial, geochemical elephantiasis) is presumed to occur from absorption of various colloid-sized elemental particles in irritant clays (eg, aluminum, silicon, magnesium, iron), which undergo macrophage phagocytosis, induce collagenization of afferent lymphatics, and obliterate them.⁶¹ Thus, transdermal exposure to and disease from certain nanoparticles is assumed established. Nanocompositions in paints and coatings, clothing, transdermal drug delivery devices, topical ultraviolet protection products, or proprietary cosmetics are of concern. Nanoparticles can be taken up by human epidermal keratinocytes and/or cause DNA damage; at issue is whether epidermal penetration to affect such damage actually occurs.^{244,300,305} Reviews summarizing TiO₂ and ZnO nanoparticles concluded that dermal

penetration for those substances was unlikely beyond the stratum corneum.^{244,245} However, TiO₂ and ZnO nanoparticles (in currently available sunscreens) can reside in the stratum corneum and follicular sink.³⁵⁹ Solvents or diseased (eg, psoriatic), injured, or mechanically stressed skin might allow increased dermal penetration.³⁵⁹ In experiments simulating heavy industrial solvent exposure, toluene, cyclohexane, or chloroform could transport C₆₀ fullerenes across the stratum corneum into viable epidermis.³⁹⁰ Epidermal and dermal penetration of a phenylalanine-based fullerene amino acid-derivatized peptide occurred via passive diffusion and was enhanced with skin flexion.²⁹⁶ Oil-water emulsion base products containing diclofenac sodium released nanoparticles capable of reaching human epidermis.³⁰⁸ Neutral, anionic, or cationic coated commercially available QDs applied to porcine skin at workday exposure doses could reach the epidermis and dermis.²⁹⁹ Silver nanoparticles cause focal, microscopic inflammation and edema and localize on the surface and in the upper stratum corneum layers when applied topically for 14 days in pigs.³⁰⁵ Near-infrared QDs intradermally injected in pigs could be followed to sentinel lymph nodes 1 cm below the skin.¹⁵⁷ Intradermally injected CdSe core-CdS capped-PEG nanoparticles remained in the skin and drained via lymphatic ducts to regional lymph nodes, and then accumulated in the liver, kidney, spleen, and hepatic lymph nodes.¹¹²

Inhalational Exposure

Nanoparticle aerosols may be generated in manufacturing or research environments. Anthropomorphic ultrafine products are encountered in welding, soldering, cooking fumes, and pollution. As the iron to carbon (soot) ratio increases in diesel combustion, the number and size of self-nucleated metallic nanoparticles and larger agglomeration of metallic and carbon particles increase.¹⁷⁴ Carbon fullerenes can be detected in flaming soot following combustion of various hydrocarbon fuels.³²¹ Combustion-derived nanoparticles carry soluble organic compounds, polycyclic aromatic hydrocarbons, and oxidized transition metals on their surface.²¹⁶ Secondary nanoparticles can form in the atmosphere via gas-to-particle conversions following nucleation and coagulation or condensation.²⁸ Intermediate particles (> 80 nm and < 200 nm) may remain suspended in air for days to weeks.³⁵⁸

Deposition of inhaled particles is determined by various factors including diffusion and inertial impaction. In rat nasal passages, computational fluid dynamics (CFD) models predicted that 3 nm particles deposited mostly in the anterior nose and larger 30 nm particles distributed throughout the nasal passages.⁹⁷ At deeper levels, gravity contributes to greater particle deposition of fine particles in the central airways instead of the lung periphery.⁶⁰ However, particles of less than 2500 nm reach the alveoli, transported from the airway duct by convective bulk flow combined with particle motion from sedimentation and diffusion.¹²⁷ Alveolar deposition models indicate a saddle-shaped, volume- and rate-sensitive curve, a minimum particle deposition at 50 microns and peak deposition at 30 nm and 4000 nm.⁵³ Consistent with theory, total deposition fraction of ultrafine aerosols in healthy human volunteers increased by as median particle diameter decreased from 100 nm to 40 nm, as tidal volume increased, and as respiratory flow rate decreased (longer respiratory and retention time).¹³⁹ Deep breathing similarly increased deposition of inhaled 100-cm³ aerosol boluses of ^{99m}Tc–radiolabeled carbon ultrafine particles. In shallow breathing, particles deposit with a greater proportion asymmetrically in the left lung, for unclear reasons.²¹⁹ While large particles or those with a high aspect ratio (ie, high length to width ratio) would not be expected to achieve deep lung penetration, “aerodynamic diameter” (D_{ae})—defined as the diameter of a sphere of unit density (1 g/cm³) with the same terminal settling velocity as the particle itself—actually determines respirability.⁷³ As D_{ae} is proportional to the fiber diameter and not to its length, “paradoxical respirability” of high aspect ratio nanoparticles can occur.⁷³

Clearance may be affected by mucociliary movement and augmented by macrophages at the alveolar level. Macrophages may either move particles toward ciliated epithelium, uptake and store particles, or contribute to transepithelial movement, whereby particles may deposit in the basement membrane or enter the lymphatics or bloodstream.^{163,199,249} Translocation demonstrates size- and species-dependence. Iridium particles (2–4 nm) crossed the air-blood barrier to reach secondary target organs to a greater extent than carbon (5–10 nm) particles, and translocation and accumulation was greater with 20 nm iridium aggregates than with 80 nm aggregates.¹⁶⁴ Soluble compounds are generally rapidly absorbed. Nanoparticles may evade effective clearance. Several studies have indicated that 15 to 80 nm particles are inefficiently taken up by macrophages (~ 20%), but are retained in epithelial cells or interstitium.²⁴⁹ Prolonged particle pulmonary persistence was seen in one human ultrafine particle inhalation study, accounting for translocation and urinary elimination.²²⁴ In an animal study, at 60 days, 81% of multiple-walled CNTs (MWCNTs) and 36% of ground CNTs administered intratracheally (0.5 mg/rat) could be recovered.²²⁶ In contrast to small particles which transit the visceral pleura, reach the pleural space, and drain into the lymphatic system through chest wall pores (3–8 μm), long nanotubes may travel and embed in the subpleural wall and within subpleural macrophages.^{74,298}

Oral Exposure

Multiple nanoparticulate systems are under evaluation for their ability to enhance solubility, permeability, bioadhesion, bioavailability, and efficacy of poorly absorbed drugs, proteins, and vaccines.^{66,269,394} Unintentional oral exposure is expected to be uncommon. Aerosol deposition in the upper aerodigestive tract could provide matter for subsequent swallowing. Nanoparticles can enter bacteria and living cells, providing a mechanism for food-chain bioaccumulation.²⁵ Nanoparticles can cross either para-cellularly (between cells) or transcellularly. Transcellular uptake is thought primarily to occur at associated lymphoid tissue, but may also occur at villi. In general, nanoparticle uptake is enhanced by smaller size and absence of charge.^{49,126} Hydrophobicity studies show mixed results (depending on altered permeation through various layers).¹⁷⁶ Similar to skin, inflamed or infected intestinal mucosa can increase permeability and alter experimental results.¹⁷¹

Single-walled CNTs (SWCNTs) ingested by *Drosophila* larvae at concentrations as low as 16 ppm traverse the gut wall, enter the dorsal vessel, and can embed in the central nervous system.¹⁷⁹ Mice exposed to ZnO powder (20 and 120 nm) at 1 to 5 g/kg showed pathological damage in stomach, liver, heart and spleen, with slightly different patterns of effect.³⁷² Orally administered TiO₂ large particles (475 nm) associated with gut associated lymphoid tissue (GALT) are translocated to systemic organs such as the liver and the spleen (6.5%).¹³⁸ Macrophages in human GALT frequently contain multiple microparticles: the food additive TiO₂ (100–200 nm), aluminosilicates (kaolinite illite, mica, smectite, or vermiculite) (< 100–400 nm), and mixed aluminum-free environmental silicates (100–700 nm in length).²⁷⁹ These correlated with chronic latent granulomatous inflammation in susceptible individuals. Water-soluble fullerenes had very poor oral absorption in one rat study. Trace amounts that did cross the gastrointestinal barrier demonstrated prolonged retention and the ability to reach brain tissue.³⁹¹ Four and 10 nm diameter colloidal gold particle uptake occurred by persorption through single enterocytes at villi in the proximal ileum, distal ileum, and in Peyer's patch regions of the small intestine.¹²⁶ Gold nanoparticles (15 nm) similarly penetrated rat intestine in a separate in vitro experiment.³²⁸ Rats fed silver nanoparticles (~ 60 nm) showed dose-dependent accumulation in kidneys, liver, brain, lungs, and blood; female rats showed more accumulation of silver nanoparticles in all kidney regions.¹⁵⁸

Internal Deposition and Degradation

Additional understanding of human-particle interactions proceeds from experience with early colloidal treatments for rheumatoid arthritis, surgical procedures, and implanted devices. Decades ago, it was demonstrated in human and animal models that gold particles of less than 20 nm could spread beyond injected joints to lymph nodes, liver, spleen, and kidneys, to induce cellular uptake, mitochondrial damage, and degenerative renal tubular lesions.^{332,397} Metallic fragments from surgical diathermy instruments can deposit in urinary tract tissues to induce granulomatous inflammation.¹²⁴ Joint replacements and spinal implants can produce particulate wear debris. Dense and loose connective tissue, giant cells, and macrophages, and phagocytosed iron and chromium particulate debris have been found surrounding stainless steel spinal implants removed due to late operative site pain.³¹⁴ In hip implants, periprosthetic tissue may contain cobalt, chromium, and bone cement wear particles.^{39,111} Local particle accumulation leads to a repetitive cycle of macrophage phagocytosis, cell degeneration and death, release of intracellular enzymes and ingested metallic debris, and tissue necrosis.³⁰⁴ Submicron mechanical wear particles (including polyethylene, titanium, alloys of titanium-aluminum-vanadium, cobalt-chromium-molybdenum, stainless-steel cobalt-chromium-nickel-tungsten, barium sulfate, zirconium oxide, corrosion products of cobalt-chromium, and stainless-steel) from patients wearing failed orthopedic replacements disseminated to lymph nodes, liver, and spleen.³⁶⁵ Lymph nodes demonstrated both granulomatous and fibrotic reactions and particle-laden macrophages; elevated serum metal concentrations and granulomatous lesions in the liver and spleen were occasionally found. Rare and severe deterioration can produce massive metallosis and systemic metal toxicity.²⁵³

Circulation, Retention, and Elimination

As indicated in the previous sections, circulatory access may occur through intravenous administration of nanoparticle pharmaceuticals, pulmonary translocation, intestinal absorption, dermal penetration, or draining lymphatics (Fig. 129–2). In human volunteers, inhaled ^{99m}Tc-labeled ultrafine carbon particles (< 100 nm) reached the blood within one minute, peaked between 10 to 20 minutes, and persisted for up to 60 minutes.²⁴¹ Both hepatic accumulation and urinary excretion occurred. Gold nanomers (30 nm) can be recovered rapidly in blood platelets of the alveolar capillaries after rat intratracheal injection.¹⁹ Aerosolized gold nanoparticles accumulated in more than 20 rat organs and tissues, particularly the lungs, esophagus, kidneys, aorta, spleen, and heart.⁴⁰²

Tight junctions (< 2 nm) between endothelial cells preclude most nanoparticles from exiting the systemic circulation. However, organ-specific endothelial characteristics (hepatic fenestrations and splenic discontinuity), transcytosis, or leak-inducing disease conditions (inflammation and cancer) may allow exit of large particles. Reticuloendothelial system (RES) and renal clearance are specific to individual particle and coating.^{161,180} Shielding nanoparticles with neutral compounds or those providing steric repulsion or hindrance is thought to impair opsonization with subsequent RES clearance.²⁵⁹ Neutral

charge may also improve renal elimination of certain dendrimers.² Size differences of as little as 2 μm may shift elimination from renal to hepatic.¹⁵⁹

DETECTION AND DOSE QUANTIFICATION

Previous sampling of generated aerosols generally focused on the average chemical composition and the mass of all deposited particles, with the exception of asbestos, for which the number of fibers with a specific shape and composition is important.²¹¹ Production of engineered nanoparticles frequently results in a distribution of sizes. Dose assessment is complicated by the multiple differences among nanoparticles and ongoing investigation as to the most appropriate metric to measure: bulk amount (total particulate mass), particle burden (number of particles of a certain size), size distribution, total surface area, surface functional groups, delivered or deposited dose (per cell or other biological unit), internalized dose, or an alternative metric. Measurement approaches include various devices to assess particle mass directly (filter collection with analysis, size-selective static sampling, tapered element oscillating microbalance) or indirectly (via various impactor technologies), direct number assessments (via electron microscopy, optical or condensation particle counters, differential mobility analyzing systems, and scanning mobility particle sizers), and surface area.^{85,101,192,211,236,237} The chosen method is critical, as mass concentration measurements can demonstrate significant variation compared to particle number counts in industrial settings.^{85,274}

TOXICITY

Overview

Certain organisms intentionally synthesize nanoparticles (eg, selenium-respiring bacteria, magnetotactic bacteria, gold nanoparticles in alfalfa).^{98,175,255} The diverse nature of the substances, compositions, structures, and physical properties involved in nanotechnology limits generalization regarding possible human effects. Representative of the knowledge gap, the US Hazardous Substances Data Bank identifies only few nanosubstances, namely, carbon black, carbon nanotubes, fullerenes, octinoxate, cerium oxide, iron, platinum, samarium oxide, silver, selenium, titanium oxide, and zinc oxide nanoparticles. Multiple reviews have attempted to address the diverse issues surrounding nanoparticle toxicity, and various schemes have been proposed to categorize nanoparticles.^{10,82,118,192,199,248,264,323} One older review reported 428 studies documenting adverse events of 965 unique nanoparticles.¹¹⁸ Reviews of a single “class” of nanoparticles have documented both adverse and neutral effects. Inference of systemic biological effects in humans is hindered by the *in vitro* nature of many experiments. Differences in experimental methodology, cell line, substance concentration, particle size and geometry, exposure parameters (route, duration, and frequency), duration of observation, and end points or surrogate markers have hindered comparisons. Data on the long-term effects are lacking. Cell-line specific, organ-specific, and species-specific toxicities remain to be fully characterized.

To address these deficiencies, methodologies are being developed to assess nanotechnology risk in a systematic fashion. Classifying nanoparticles based on the results of multi-dose-range biological assay profiles (ATP content, reducing equivalents, caspase-mediated apoptosis, and mitochondrial membrane potential) in multiple cell lines has been advocated.³²⁰ Other techniques to evaluate toxicity and biologic reactivity of nanoparticles have been reviewed and include cellular proliferation, necrosis, and apoptosis assays; reactive oxygen species (ROS) generation and oxidative stress; activation of proinflammatory signaling or other messenger molecules; genotoxicity and gene expression analysis; and *in vivo* exposure route, short and long term effects, tissue localization, biodistribution, and clearance studies.^{207,326,334} Studies and models of quantitative structure-activity relationships (QSAR) may take on more importance to profile toxicity as the number of compounds proliferates.^{286,381}

Despite the many unknowns, antecedent work within the discipline of particle toxicology has provided extensive epidemiologic and experimental evidence associating airborne pollution particulate matter (PM) with human mortality, cardiovascular, pulmonary, neurologic, and reproductive injury, altered neurocardiac function (decrease heart rate variability and repolarization), and malignancy.^{36,67,71,153,268,272,297,366,403} The strength of the association depends on the particle size, type, and the outcome of interest. Similarly, ultrafine particles in home-generated cooking fumes have received attention for their possible role in pulmonary disease, inflammation, and genotoxicity.^{217,326,327,369,386}

Genetic or unique susceptibilities to nanoparticles are not well categorized. Preexisting acute or chronic disease (pulmonary disease, cardiac disease, malignancy, infection) or individual genetic variations (resistance to oxidative stress, immune composition, surface or serum proteins) may modify nanoparticle toxicity. For example, following identical ultrafine particle aerosol exposure, patients with chronic obstructive pulmonary disease (COPD) received an increased “dose” (deposition factor and/or rate) compared to normal individuals.³⁸ Retention of ultrafine particles was similarly higher in patients with COPD than healthy nonsmokers.²²⁴ Patients with preexisting cardiovascular disease or older age show increased susceptibility to concentrated ambient air pollution particles.⁶⁷

Although the following sections generally report “positive” studies in order to highlight nanotoxicity principles, it is important to acknowledge that many other studies have also produced negative results, and some have challenged the concept of “nano-specific” toxicity.⁷³ Toxicities identified experimentally must be coupled with an understanding of physicochemical properties (which impact organism and environmental transport) and exposure assessments in order to appropriately characterize risks.

Dose

Depending on the nanosubstance, “dose” (particle number or bulk amount) may or may not play a role. Appropriate dose-response curves (linear, supralinear, biphasic, or threshold) for different toxic effects have not yet been described for most particles.²⁴⁹ For example, anti-HER2 antibody-tagged silica-gold nanoshells showed no inherent in vitro toxicity to breast adenocarcinoma cells over a range of concentrations and exposure durations.¹⁸⁹ CdSe/ZnS QDs encapsulated in phospholipid block-copolymer micelles injected into *Xenopus* blastospheres were “nontoxic” until doses of 5×10^9 nanocrystals/cell produced “abnormalities.”⁷⁶ CdSe/ZnS QDs at higher doses (20 nM/L) increased apoptotic cell death and cytokine release.²²⁹ The principal toxic mechanism changed from intracellular oxidative stress to cadmium ion release as QD concentration increased in another study.¹⁸² Dose-dependent cytotoxicity was seen in human keratinocytes as SWCNT concentration increased from 0.11 to 10 $\mu\text{g/mL}$.²⁰⁴ Dose- and time-dependent effects were apparent in human peripheral blood lymphocytes exposed to oxidized or pristine MWCNTs.³⁰ Nano-SiO₂ caused cytotoxicity and induced the apoptotic pathway in dose- and time-dependent manners.³⁹⁸ In zebrafish embryos, silver nanoparticles induced dose-dependent embryotoxicity and multiple developmental abnormalities.¹⁷⁸ Silver nanowires show dose-dependent cytotoxicity from 1.9 to 1900 $\mu\text{g/mL}$ in human laryngeal epithelial and cervical carcinoma cells.¹ Carbon black and fullerene (C₆₀) manufactured nanoparticles were genotoxic in vitro and in vivo in a dose-dependent manner.³⁵³

Size and Surface Area

Despite a comparable exposure on a mass-for-mass basis, nanoparticle toxicity may diverge significantly from bulk material. This may occur due to several factors including increased surface area, chemical reactivity, or ionization; altered absorption profiles; altered cellular interactions; or access to “protected” intracellular spaces. Cobalt-ferrite particles (6 nm) were more cytotoxic and genotoxic than 10 or 120 μm particles.⁵⁵ Cytotoxicity of amorphous silica particles increased 33-fold as particle size decreased from 104 nm to 14 nm.²³⁵ Elemental carbon particles (5–10 nm) induced significantly more inflammatory mediators than larger carbon black particles (14 or 51 nm).¹⁶ CoCr nanoparticles generate more superoxide and hydroxyl free radicals and more DNA damage than CoCr microparticles, possibly due to faster dissolving or corrosion within the cell.²⁶² TiO₂ nanotubes (diameter 15–30 nm) permitted the best cellular adhesion, migration, viability, and differentiation compared to larger 50 nm nanotubes.²⁶⁶ CdTe QDs of approximately 2, 4, and 6 nm had over a six-fold difference in inhibition of human hepatoma cell growth.⁴⁰⁵ CdTe QDs (2.1 nm) can rapidly enter the nucleus of human macrophages and gold nanoparticles (1 nm) can penetrate cell and nuclear membranes.^{231,356} CdTe QDs (2.2 nm) were more cytotoxic than equally charged, larger QDs (5.2 nm).¹⁹³ Nano-tungsten carbide-metallic cobalt particles (~80 nm) generated more hydroxyl radicals, induced greater oxidative stress, and caused faster cell growth/proliferation than fine (4 μm) particles.⁶⁸

Composition

Toxicity may be primarily related to that of the bulk material. Elemental carbon particles (90 nm) were found to be significantly more toxic than diesel exhaust particles of comparable size (120 nm).³²⁰ Redox-active transition metals may pose a particular hazard.⁷³ Gold, chrysotile asbestos, Al₂O₃, Fe₂O₃, ZrO₂, and TiO₂ nanoparticles differed in cytotoxicity in murine lung macrophage cells.³³⁰ QD core materials (cadmium, lead, selenium) can be toxic at relatively low concentrations to the plasma membrane, mitochondrion, and nucleus.^{52,120,194} Degradation of coated nanoparticles in the acidic and oxidative conditions of endosomes and lysosomes may result in exposure to inherently toxic core materials or ions. Derivatization or degradation may mitigate or exacerbate toxicity. Functionalization with quaternary amines prevented silica mesoporous nanomaterial-induced cellular injury.³⁴² Conversely, compared to “pristine” SWCNTs, acid-functionalized SWCNTs blocked cell cycling of murine lung epithelium cells, and produced a more pronounced inflammatory response in mouse lungs in vivo.³⁰⁹ Similarly, oxidized MWCNT were significantly more toxic to human T cells than their “pristine” counterparts or carbon black.³⁰ Decay of certain water-soluble fullerenes produces daughter compounds with increased toxicity in vivo.²⁰

Contaminants

Contaminants may introduce or mitigate toxicity. “Doping” intentionally introduces impurities in order to modify the behavior of materials (eg, electrical properties of semiconductors). Similarly, doping can change the electronic, optical, and magnetic properties of nanocrystals.²⁴⁶ Nitrogen doping of MWCNTs improved biocompatibility and reduced lethality in mice exposed via multiple routes.⁴³ Nitrogen-doped MWCNTs also proved more biocompatible in *E. histolytica*.⁸¹

The manufacturing process may unintentionally instill contamination—atomic or molecular impurities in the nanomaterial structure itself, residual reagents or catalysts, or manufacturing byproducts. Even “purified” SWCNTs retain significant percentages of cobalt, molybdenum, iron, nickel, yttrium, and zinc.^{170,203} Consequentially, non-purified, iron-rich SWCNTs (26 wt.% of iron) generated hydroxyl radicals and lipid hydroperoxides and depleted GSH more than “purified” SWCNTs (0.23 wt.% of iron).¹⁴⁴ Purified fullerenes generate significantly less biological oxidative damage and adverse mitochondrial effects than unrefined fullerenes.^{17,285} Residual contaminants and impurities of substances used in surface modification of QDs are cytotoxic and genotoxic in vitro.¹³⁰ Washing off unbound cetyltrimethylammonium bromide eliminated near total lethality of gold nanoparticles modified with this compound.⁵⁶ Single walled carbon nanohorns, prepared from pure graphite without a metal catalyst, showed no skin irritation, eye irritation, or perioral toxicity.²¹⁸

Coating and Surfactant Materials

Coating materials may shield toxicity of core compounds or possess inherent toxicity. They can mediate biocompatibility, duration of circulation, and organ- or cell-specific uptake. For example, various densities of electrostatic poly(glutamic acid)-based peptide coatings altered delivery of cationic polymer-plasmid DNA nanoparticles to liver, spleen, and bone marrow.¹²¹ QDs coated with carboxylic acids, amines, or PEG increased uptake by human epidermal keratinocytes in that order, with carboxylic acid-coated QDs demonstrating cytotoxicity 24 hours earlier.³⁰⁰ Nanoparticle cores of 2-diethylamino ethyl methacrylate polymerized with poly(ethylene glycol) dimethacrylate were significantly more toxic to dendritic cells than cores surrounded by a 2-aminoethyl methacrylate shell.¹³² Upon inhalation, SiO₂-coated rutile TiO₂ nanoparticles but not uncoated rutile or anatase or nanosized SiO₂ induced pulmonary neutrophilia and inflammatory markers.²⁹⁵

Conversely, covalent materials may reduce toxicity. Carboxylic acid grafting of cobalt-ferrite nanoparticles reduced toxicity by reducing leaching of Co²⁺ into solution.⁵⁵ Gelatin coating reduced (but did not eliminate) cytotoxicity of CdTe QDs in human acute monocytic leukemia cells.⁴⁰ PEG substituted CdSe core/CdS shell QDs were less cytotoxic extracellularly than “bare” QDs.⁴⁵ However, some benign coatings can be rendered cytotoxic by air exposure or photodecomposition.⁶⁵

Nanoparticles tend to aggregate due to attractive forces (van der Waals), and become progressively difficult to re-disperse as size decreases.²⁸⁰ SWCNTs agglomerations induced significantly more adverse effects than identical, well-dispersed SWCNTs.³⁷⁹ As CNTs are intensely hydrophobic, solvents or surfactant materials are used to disperse them and avoid clumping, although these materials themselves may be cytotoxic.³⁷⁹ Exposure to protein rich biological fluids may change the tendency to agglomerate, and therefore produce size-dependent effects. Using surfactants to disperse nanoparticles (eg, SWCNTs) can decrease protein adherence, and therefore alter biological effect or fate.^{78,103}

Geometry and Architecture

Nanoparticle geometry may modulate toxicity and biological interactions. Previous observations suggested that toxicity might vary with the type of crystalline structure of a given material. For example, asbestos particle shape affects genotoxicity, and inflammatory and mutagenic properties vary by silica type (crystalline or amorphous).³¹¹ Identical concentrations of various aluminosilicate zeolite crystals (erionite, mordenite, and synthetic zeolite Y) of 0.1 to 10 micron size produced variant cytotoxicity and hydroxyl radical generation in rat lung macrophages.⁸⁶ Material surface defects are important for ROS generation: amorphous TiO₂ crystals were found to generate significantly more ROS than anatase, mixed anatase/rutile, or rutile crystals.¹⁴⁰ In a separate analysis, nano-TiO₂ (anatase) generates more biological oxidative damage than nano-TiO₂ (rutile),¹⁷ and generally anatase nano-TiO₂ is more photocatalytic than the rutile form.³⁵⁹

High aspect ratio is thought to contribute to nanoparticle pulmonary toxicity, including penetration of the alveolar wall and visceral pleural.^{73,215} SWCNT produced pulmonary granulomata and inflammation, whereas nanoparticle carbon black did not.^{17,203,325} “Long” (825 nm) CNTs, which were less easily enveloped by macrophages than their 220-nm counterparts, increased the degree of inflammatory response in rats.³⁰⁷ Asbestoslike pathology was also seen for “long” MWCNT (nanometer diameter, 15+ μ m length) in mice.²⁷⁶ In mice, single wall nanohorns showed significantly less toxicity than SWCNTs.¹⁹⁷ Nanofibers and graphene nanoplates with high aspect ratios but low aerodynamic diameter can persist to frustrate macrophage engulfment and contribute to toxicity.³¹² However, gold nanorods had significantly less cellular uptake than comparable spherical structures.⁵⁰ This geometry dependence was reversed upon PEGylation.²⁰² Attachment by

HepG2 cells to micelles with PEG copolymer films varied depending on whether PEG polymer was in a “brush” (anchored at one end) or “mushroom” (anchored at both ends) conformation.¹³² Compared to control wafers of the same composition, Fe-Co-Ni nanowires hindered macrophage growth and development.³ Dendritic clusters consisting of aggregated 60 nm nickel nanoparticles produced higher embryonic toxicity than spherical 30-, 60-, and 100-nm particles of the same material.¹³⁶

Additionally, nanoparticles may adsorb varying layers of surrounding biological proteins or lipids, altering effective size, shape, and density. Curvature and size of the nanoparticle may affect the extent of this “corona” and influence interactions with bound proteins such as albumin, apolipoprotein, and complement which may effect cells entry or receptor interactions.^{196,310} Bioassociation may also change nanomaterial properties. ZnO nanoparticles changed particle size, distribution, and charge in the cell culture media.³⁷⁵ SWCNTs adsorbed with serum proteins (primarily albumin) had an antiinflammatory effect, which was lost when surfactant-treated SWCNTs precluded adsorption.⁷⁸ The same authors found, in contrast, prevention of protein adsorption to amorphous silica particles reduced toxicity.

Charge

Surface charge (zeta potential, ζ P) may significantly alter the physical characteristics of nanoparticles, biological interactions, or effects. Neutral SWCNTs aggregate in aqueous solution; introducing a strong negative charge induces dispersal.³⁰⁹ Negatively charged nanoparticles permeated model pig skin, which excluded positively charged and neutral particles.¹⁶⁰ Increasing surface charge density alters protein absorption; a positive charge promotes electrostatic association with negatively charged serum proteins.^{102,121} Charged nanoparticles are recognized as important inducers of complement activation.⁶⁹ Strongly charged particles can also mediate direct membrane damage (hole formation) in the lipid bilayer.^{128,129} Positively charged polystyrene nanospheres induced oxidative stress, those with neutral charge did not.³⁸⁹ Toxic effects of strongly negatively charged acid-functionalized SWCNTs were abrogated by pretreatment with neutrality-inducing L-lysine.³⁰⁹ Positive charge mediates actin-dependent amorphous silica nanoparticle movement along filopodia and microvillilike structures.²⁵⁷ Mouse peritoneal macrophages and human hematopoietic monocytic cells show charge-dependent endocytosis—the higher the negative or positive surface charge of albumin particles, the greater the uptake.²⁹⁴ An overlap of the conduction band energy (E_c) level of metal oxide nanoparticles with the cellular redox potential (−4.12 to −4.84 eV)—which signifies the permissibility of electron transfers in biological environments—correlated with induction of oxygen radicals, oxidative stress, and inflammation.⁴⁰⁴ Also, within lysosomes, positively charged nanoparticles are capable of acting as “proton sponges,” enhancing cytoplasmic delivery and inducing cell death signaling.³¹⁷

pH

pH might be expected to effect toxicity by altering charge, solubility, protective or functional groups, bioavailability, and other mechanisms. pH alters the zeta potential of both microemulsion (3–5 nm) and hydrothermal (8–10 nm) cerium oxide nanoparticles, which in turn alters protein adsorption and cellular uptake.²⁶⁷ The significant toxicological difference in mice between 23.5 nm and 17 μ m copper particles was judged secondary to stomach retention, with persistent depletion of H^+ ions leading to systemic metabolic alkalosis and generation of ionic copper.²¹⁴ CdSe core QDs exposed to low-pH simulated gastric fluid decreased cell viability in vitro, possibly due to degradation of the ZnS shell and increased solubility of cadmium from shell-free particles.³⁷³ Acidic intracellular organelle localization raises degradation and damage concerns; the inflammatory potential of 15 metal/metal oxide nanoparticle correlated with acidic conditions, hypothesized to be related to elimination of the corona in lysosomes to expose a charged surface.⁵¹ Targeted drug delivery employs intentional engineering of pH-responsive nanoparticles. In the acidic environment of the endosome or lysosome (~ pH 4.5), core-shell particles can swell by almost 3 times, disrupting these structures and allowing cytosolic entry.¹³² Alternatively, at altered pH, certain functional groups can be cleaved, resulting in altered charge and improved QDs delivery.²²¹

Cellular Toxicity

At the cellular level, nanoparticle toxicity has been attributed to multiple mechanisms (Fig. 129–3). Oxidative stress, membrane and cytoskeleton structural alterations, cytoplasmic and nuclear protein interactions, energy failure, phototoxicity, and genotoxicity have all been described. Nanoparticles may stress cell types differently. This may be due to engineered properties (associated targeting molecules), properties of nanomaterials themselves (size-dependent reticuloendothelial system deposition), or biological processes of target cells (eg, phagocytosis ability, resistance to oxidative stress, cytoskeletal architecture, cell division propensity). Tests in immortalized cell lines may not reflect in vivo findings due to inherent differences in genomic stability or specifically selected traits.

FIGURE 129-3. Potential mechanisms of nanoparticle cellular toxicity. $\Delta\psi_m$ = mitochondrial membrane potential, DNA_{mt} = mitochondrial DNA; His = histone; MPTP = mitochondrial permeability transition pore; RNS = reactive nitrogen species; ROS = reactive oxygen species.

Uptake. Unintended cellular uptake may contribute to toxicity. Depending on the particle architecture, several mechanisms have been described, including phagocytosis/endocytosis (clathrin-mediated scavenger receptor-mediated, mannose receptor-mediated, Fcγ receptor-mediated, complement receptor-mediated), potocytosis (caveolin dependent), (macro)pinocytosis, and direct cytoplasmic entry^{70,99,239,265,322,348,362} Various types of ammonium-, acetamido-, fluorescein isocyanate-, and methotrexate/fluorescein isocyanate-functionalized SWCNTs and MWCNTs were internalized by a wide range of cell lineages (mammalian, fungal, yeast, and bacterial), some of which lack phagocytic and endocytic capacity, and under conditions which block energy dependent pathways¹⁶² Dextran-coated supermagnetic iron oxide (SPIO) nanoparticles are taken up by human monocyte-macrophages and concentrated into lysosomes in a nonsaturable manner²²⁸ Nonendocytic uptake (eg, 78-nm fluorescent polystyrene microspheres and 25-nm gold particles) provides nonmembranebound nanoparticles direct access to intracellular proteins, organelles, and DNA¹⁰⁰

Engineered nanoparticles, which are capable of endocytosis, would be expected to translocate to distant sites within the body.⁸²

Oxidative Stress. Oxidative stress with subsequent lipid peroxidation, DNA damage, and apoptotic or necrotic pathway induction is a significant concern. Biologic oxidative damage as assessed by the ferric reducing ability of human serum revealed a diverse capacity for oxidative potential among nanoparticles.¹⁷ Metal oxide nanocompounds (eg, Co_3O_4 , Cr_2O_3 , Ni_2O_3 , Mn_2O_3 , and CoO) capable of electron transfers effectively produce oxygen radicals and oxidative stress.⁴⁰⁴ Research findings are complicated by differences in generation of reactive oxygen species (ROS) under abiotic conditions

versus intracellularly.³⁸⁹ Biological mediums may also alter ROS generation.⁹² In neuroblastoma cells CdTe QDs induced lipid peroxidation and Fas cell death receptor upregulation, which could be mitigated by capping QDs with N-acetylcysteine.⁵² Adult zebrafish raised in solutions containing silver nanoparticles demonstrated oxidative injury, apoptosis, and cellular stress response (eg, GSH and p53 induction).⁵⁴ Fullerenes have shown more conflicting results. Depending on experimental conditions and purity, they may either induce $O_2^{\bullet -}$ and OH^{\bullet} or possess antioxidant (and antiperoxidation) activity.^{104,392} SWCNTs and tungsten carbide-cobalt nanoparticles generate ROS and activate pathways leading involved in cytotoxicity and neoplastic transformation.^{68,204}

Organelle and Substructure Damage. Nanoparticles may compromise diverse subcellular components. Mitochondrial reduction capacity (eg, MTT assay) is one of the standard in vitro methods to assess nanoparticle toxicity. Nanoparticles' mitochondrial toxicity includes alterations in mitochondrial calcium levels, dissipation of the mitochondrial membrane potential, lipid membrane destruction, and localization within the mitochondria.^{52,194,260,389} Small gold nanoparticles (3 nm) can access the voltage-dependent anion channel (porin) to cross the mitochondrial membrane.³⁰¹ Induction of the mitochondrial base excision repair pathway enzymes suggests that MWCNTs can induce mitochondrial DNA damage.⁴⁰⁶ Polyamidoamine (PAMAM) dendrimers (45 nm) can down-regulate mitochondrial DNA-encoded genes involved in the maintenance of mitochondrial membrane potential and caused the release of cytochrome C, triggering apoptosis.¹⁷⁷

QDs (2.1 nm) have been visualized to localize rapidly (< 30 minutes) and preferentially in the nucleus of human macrophages, mediated by endosomal transport along microtubular tracks.²³¹ Co_3O_4 nanoparticles (45 nm) readily enter cells and their nucleus in vitro.²⁶³ SWCNTs can accumulate in the cell nucleus by crossing the lipid bilayer.²⁷⁷ Genotoxic consequences of this migration are described later.

Nanoparticles may cause disruption and compromise integrity of biological membranes by such means as hole formation in the lipid bilayer.^{128,129} Alteration in cellular adherence, migration, and actin cytoskeleton or microtubule function and structure have been described following exposure to SWCNTs, gold/citrate, TiO_2 , and SPIO nanoparticles.^{95,106,113,145,270} Calcium-mediated cytoskeletal function (as evidenced by cell stiffening) was altered by ultrafine carbon particles (12 nm, 90 nm) but not by diesel exhaust or urban dust particles.²²³ Functional processes may be impaired in the absence of the loss of viability. SiO_2 , TiO_2 , Ag, and Au, alone or functionalized with either positive or negative side chains, altered exocytosis and decreased secretion of chemical messenger molecules.^{191,209} Other protein functions may also be altered by nanoparticles. Copper nanoparticle clusters selectively induced unfolding and precipitation of hemoglobin A0 and E, whereas almost none occurred with hemoglobin A2.²⁴ Nanoparticulate anatase TiO_2 (5 nm) can directly bind lactate dehydrogenase and induced protein unfolding.⁷⁵ C_{60} fullerene noncompetitively inhibits glutathione peroxidase in a substrate-specific manner.¹³⁷ While relatively high concentrations were required (250 μM), the C_{60} fullerene derivative, dendrofullerene, selectively inhibited P450 metabolism of progesterone.⁹¹ Modification of protein structures by reactive nanoparticles might also serve as a mechanism for haptene formation and immunoreactivity.

Gene Expression and Genotoxicity. Overwhelming nanoparticle toxicity can induce a cascade of expression of genes involved in either apoptotic or necrotic pathways. Nanoparticles can also upregulate stress-and inflammation-related genes as well as alter expression of genes involved in the cytoskeleton, trafficking, protein degradation, metabolism, growth and division, and detoxification. As a consequence of direct nuclear entry, nanoparticles can aggregate within the nucleus, bind directly to DNA or chaperone proteins, or induce nuclear membrane damage. Gold clusters (1.4 nm) present in growth media can access and directly associate with the major grooves of DNA to induce complete cell death in multiple carcinoma cell lines at concentrations at which cisplatin is only 10% effective.^{260,356,382} Nanosilver materials similarly bind with E coli genomic DNA.³⁹⁶ Some QDs can target histones.²³¹ Other nanoparticles (eg, SiO_2) can cause clustering of critical enzymes such as topoisomerase I and sequestration of nuclear proteins (histones, splicing factor SC35, nucleolar protein fibrillarin, promyelocytic leukemia body protein PML, and p80 coilin), altering subnuclear architecture.⁴⁸ DNA damage also occurs through induction of ROS.²²²

Nanoparticle damage may be addressed by base repair and other restorative mechanisms or may be so severe that DNA strand breaks, genome duplication or deletion, chromosomal instability, aneuploidy, malignant transformation, and proliferation occur in vitro and in vivo.^{133,355,406} Poorly tumorigenic or benign cells can acquire aggressive metastatic capacity when exposed to TiO_2 nanoparticles.²⁵⁴ Alternatively, premature senescence was recently described using a C_{60} carboxylated adduct. Such an ability could be protective as a tumor suppression mechanism or compromise organ systems function.⁹⁶

Photothermal Toxicity. Nanoparticles containing photo-reactive dyes or intrinsic photothermal properties are useful for imaging and attractive for targeted chemotherapy. The approved liposomal verteporfin (benzoporphyrin derivative monoacid ring A) generates 1O_2 following activation by low-intensity nonthermal laser light (689 nm). This is believed to induce cell death and prevent the loss of visual acuity in patients with subfoveal choroidal neovascularisation.¹⁵¹ Similarly, dextran-iron oxide nanoparticles linked to a photosensitizer which generates singlet oxygen caused complete cell death

when exposed to specific light wavelengths²¹³ Nonmetal graphene QDs irradiated with blue light (470 nm) generated reactive oxygen species, including singlet oxygen, and killed human glioma cells by causing oxidative stress mechanism²⁰⁶ C₆₀(OH)_{22–26}, a water-soluble C₆₀ derivative under investigation as an antitumor, antibiotic, and drug delivery compound, was only mildly cytotoxic in the dark, but was significantly phototoxic to human lens epithelial cells via both type 1 (free radical) and type 2 (singlet oxygen) mechanisms under visible light³⁸⁰ The concern is that ambient electromagnetic radiation could excite nontherapeutic nanoparticles to generate either ROS or thermal injury. Photolytic conditions have rendered coatings unstable, exposing toxic core metal components¹²⁰ Irradiation of TiO₂, which can act as a photocatalyst, yields both oxidation and reduction reactions⁹⁴ Gold/citrate nanoparticles (13 nm) were capable of easily crossing human dermal fibroblast membranes and absorbing UV radiation²⁷⁰ C₆₀ fullerenes can generate ROS in the presence of visible light under physiologic conditions³⁹³ The ROS extent depended upon C₆₀ aggregation and associated stabilizing molecules in the aqueous phase¹⁷⁶

A host of miscellaneous cellular effects are still being characterized. Alterations in cellular resting membrane potential and ion channel functioning by metallic and carbon-based nanoparticles are a particular concern in neuronal tissue.^{18,185} Silver nanoparticles caused conformational changes of neuronal voltage-activated sodium currents and produced a hyperpolarizing shift and delayed recovery from inactivation.¹⁸⁶ QDs can provoke intracellular lipid droplet formation due to accumulation of newly synthesized lipids and down-regulation of the β -oxidation of fatty acids.²⁸⁴ SPIOs can generate intracellular gas vesicles.²⁰¹

Organ Systems Toxicity

Central Nervous System. A significant concern is the ability of nanoparticles to access “protected” spaces, such as the brain, the eye, and the reproductive tract. While targeted CNS drug delivery and imaging using engineered nanoparticles via intranasal or intravenous administration shows promise^{88,150} unintended access is worrisome

Seventy years ago, intranasal inoculation of small viral (nano)particles (the poliomyelitis virus, 25–30 nm) were shown to produce extensive polio invasion of the olfactory bulbs and lesions extending in a continuous series to the brain stem and beyond.^{26,27,131,354} Other small viruses (vesicular stomatitis, herpes simplex, and rabies virus) also access retrograde transport from the olfactory bulb to reach deeper brain structures.²⁹⁰ Anthropomorphic and engineered nanoparticles also may utilize this mechanism, with variable efficacy. Nanogold particles injected into rabbit olfactory areas demonstrated a direct connection between the olfactory bulb and the CSF.⁵⁸ Intranasal instillation of SiO₂-nanoparticles in rats led to wide distribution, striatal deposition, and a reduction in dopamine activity.³⁸⁵ In inhalation-exposed rats, ultrafine elemental ¹³C particles translocated into axons of the olfactory nerve.²⁵⁰ Rats exposed to aerosolized gold nanoparticles (20 nm) experienced particle distribution to the olfactory bulb and entorhinal cortex.⁴⁰² Rats exposed to poorly soluble manganese oxide ultrafine particles (30 nm) showed olfactory bulb uptake and CNS delivery to the striatum, frontal cortex, and cerebellum.⁷⁹ Other animal models demonstrated that cadmium, cobalt, manganese, mercury, nickel, and zinc reach the olfactory bulb when applied intranasally, and neuronal connections carry cobalt, manganese and zinc into deeper brain structures.^{35,123,271,352} Children and dogs exposed to pollution show prefrontal white matter hyper-intense lesions, associated with significant cognitive deficits in children. Ultrafine particulate matter deposition, vascular pathology, and neuroinflammation were evident in the dogs.⁴¹ Chronic respiratory tract inflammation might further diminish nasal respiratory and olfactory barriers and contribute to brain inflammation.²⁷³

Circulating nanoparticles may reach the brain. The blood–brain barrier (BBB) might be infiltrated via low density lipoprotein (LDL)–receptor mediated transcytosis of nanoparticles with nonspecific apolipoprotein adherence, endocytic processes, paracellular aqueous diffusion, or transcellular lipophilic diffusion.^{88,316} Intravenously administered water-soluble fullerene and intra-abdominally injected nano-TiO₂ (5 nm, anatase) migrate to brain in experimental models.^{88,391} Nanoparticle entry can produce CNS inflammatory changes, inflammatory gene expression, demyelination, oxidative stress, lipid peroxidation, NO generation, and altered mitochondrial energy production.^{42,79,188,198,318} Cyclooxygenase-2, interleukin-1 β , and CD14 upregulation in the olfactory bulb, frontal cortex, substantia nigrae, and vagus nerves and disruption of the BBB associated with particulate matter deposition were reported in patients exposed to high chronic pollution levels.⁴² Similarly, intravenous and intraperitoneal administration in rats of engineered silver, copper, and aluminum nanoparticles disrupted the ventral brain and proximal frontal cortex BBB to produce brain edema.³¹⁸

Nanoparticles can contribute to secondary excitatory neurotoxicity. Intranasal delivery of carbon black (14 nm) increased olfactory bulb excitatory glutamate levels.³⁵¹ Similarly, nano-Ag increased spontaneous excitatory postsynaptic currents and network activity.¹⁸⁷ Given the number of CNS and systemic human amyloidoses, a concerning finding was that polymer nanoparticles, quantum dots, carbon nanotubes, and cerium nanoparticles all greatly enhanced the rate of β_2 -microglobulin amyloid fibrillation by decreasing lag time for nucleation.¹⁸⁴ Chronic dietary exposure to TiO₂ nanoparticles

in juvenile rainbow trout led to brain accumulation and 50% inhibition of Na⁺-K⁺-ATPase activity, which did not recover following removal from exposure.²⁸⁸

Pulmonary System. The lungs are expected to be the major portal of entry for anthropomorphic nanoparticles and engineered nanoparticles in manufacturing or research settings. Concerns include nanoparticle accumulation and persistent, acute and chronic inflammation, and surfactant disruption. In the bronchial airways, 24 hour retention depends on size fraction, which is negligible for particles greater than 6 µm but increases to 80% at 30 nm.¹⁶⁵ In vitro studies show a variety of effects depending on the particle and experimental model. Canine and human alveolar macrophages uptake of elemental carbon particles (5–10 nm) induced lipid mediators AA, PGE₂, LTB₄, and 8-isoprostane in a dose-dependent fashion.¹⁶ SWCNTs activated alveolar macrophages, SWCNTs and C₆₀ fullerenes disrupted plasma membranes, and SWCNT and MWCNTs effected antigen processing, presentation, and activation of T lymphocytes.¹¹⁶ In rat alveolar type 2 and epithelial cells as well as in human bronchial epithelial cells nanoparticulate carbon black particles (14 nm) induced dose-dependent proliferation via EGF-R and β1-integrin membrane receptors, phosphoinositide 3-kinases, and the protein kinase B (Akt) signaling cascade.³⁶³ Cerium oxide nanoparticles can be taken up by human fibroblasts.¹⁸³ However, 3 hour exposures to aerosols of this fuel additive, while increasing catalase activity and minimally decreasing glutathione, did not alter cell viability, ATP content, TNF-α production, glutathione peroxidase activity, or superoxide dismutase activity in rat lung slices.⁸⁷ Combustion-derived nanoparticles of organic compounds (1–3 nm) were mutagenic in Ames tests.³¹⁵ Positive evidence for carcinogenicity of inhaled nanoparticles has been summarized.²⁹³

All types of carbon nanotubes and nanofibers are considered a respiratory hazard by the National Institute for Occupational Safety and Health (NIOSH).²³⁸ Carbon nanotubes can produce a variety of adverse effects in animal models: upper airway mechanical blockage, occlusive airway granulomas, macrophage uptake and inter-macrophage carbon bridges, abnormal macrophage mitoses, type I pulmonary epithelial cell damage, lymphocytic proliferation, multifocal granulomas, aggregation in alveolar spaces and interstitium, increased inflammatory and oxidative stress biomarkers, fibrinogenic reactions, alveolar wall thickening, bronchiolar epithelial cell hypertrophy, and peribronchial inflammation.^{143,170,203,226,238,324,374} At high doses, mice exposed to MWNTs orally, intraperitoneally, or via nasal installation showed essentially no tissue response, whereas intratracheal administration showed dose-dependent pulmonary tissue invasion, inflammation and granuloma formation, and death.⁴³ Mice aspirating 40 µg of SWCNT and acid-functionalized SWCNTs had significantly higher BAL cell counts, PMNs, and cytokines (IL-6, TNF-α, and MIP2).³⁰⁹ Also of concern are MWCNT retention, persistent inflammation, and asbestoslike effects suggested by in vitro and in vivo experiments.^{275,298,330} A systematic review of 54 animal studies indicated that carbon nanotubes and nanofibers caused adverse pulmonary effects including inflammation (44 of 54 studies), granulomas (27 of 54), and pulmonary fibrosis (25 of 54), which were similar to other fibrogenic materials such as silica, asbestos, and ultrafine carbon black.²³⁸ Mice receiving both a known initiator chemical plus inhalation exposure to MWCNT were significantly more likely to develop tumors (90% incidence) and have more tumors than mice receiving the initiator chemical alone, suggesting that MWCNT can increase the risk of cancer in mice exposed to a known carcinogen.²³⁸

While rats exposed to C₆₀ fullerenes nanoparticles (55 nm) for 10 days did not have visible of microscopic pathological lesions, particle burden and BAL protein concentrations were elevated.¹¹ Intratracheally delivered single wall nanohorns generated no inflammatory response, although nanohorns accumulated and persisted.²¹⁸ Intratracheal instillation of ultrafine (< 200 nm) particles from combusted coal induced a higher degree of neutrophil inflammation and cytokine levels than did the fine or coarse particles.¹⁰⁹ Rats intratracheally instilled with ultrafine carbon black or TiO₂ demonstrated neutrophil recruitment, type 2 epithelial cell damage, cytotoxicity, impaired macrophage phagocytic ability, and enhanced macrophage sensitivity to chemotactins.²⁹¹ A summary of nanosized TiO₂ particle effects concluded that the crystalline form has the greatest impact on pulmonary responses, whereas particle surface area, alumina or amorphous silica coating, and shape have lesser influences on toxicity.¹⁹⁹ Nasal instillation resulted in neutrophil recruitment. Alveolar macrophages took up inhaled elemental silver nanoparticles, and deposition in the alveolar wall was noted.³³⁹ While particles were rapidly cleared from lungs, there was evidence of circulatory spread. Longer-term studies showed significant silver lung persistence, chronic macrophage accumulation and alveolar inflammation, and systemic distribution.³³⁷ The severe toxicity of air-generated polytetrafluorethylene (PTFE fumes) can be reduced by aging, filtering, and preexposure, suggesting nanoparticle upregulation of pulmonary inflammatory cytokines and antioxidants.¹⁴²

Pulmonary surfactant provides low surface tension and can identify and bind targets for phagocytosis. Independent of cellular effects, in vitro lung models suggest that nanoparticle deposition may cause pulmonary surfactant dysfunction during the breathing cycle.¹⁴⁸ The collectins (phagocytosis enhancers), human surfactant protein-A and -D, bind double wall carbon nanotubes in a calcium-dependent manner.³⁰³ Diesel exhaust particulate matter can be solubilized and dispersed in the major component of pulmonary surfactant (dipalmitoyl phosphatidyl choline) and induce genotoxicity in multiple different assays in bacteria and mammals.^{303,370}

A report of uncontrolled workplace exposure to polyacrylic ester nanoparticles and other materials causing retained

intracellular nanoparticles, pulmonary inflammation, pulmonary fibrosis, and pleural foreign-body granulomata was criticized for lack of causality and differential diagnosis.^{32,329} Similarly, a report of submesothelial deposition of carbon nanoparticles after toner exposure has been criticized for lack of plausibility and causality.^{347,378}

Cardiovascular and Hematological Systems. Ultrafine particles can alter human cardiac function (decreasing heart rate variability and repolarization^{67,119,350,367,403} Heart rate variability provides a measure of cardiac autonomic control; a decrease predicts mortality in subjects with prior myocardial infarction³⁵⁰ Significant pulmonary inflammation is not a prerequisite, although autonomic reflexes from pulmonary nerve endings may mediate these effects¹⁰⁵ Jugular vein or femoral artery administration of silver, copper, and aluminum nanoparticles immediately but transiently slows heart rate³¹⁸ Engineered nanoparticles made of flame soot (Printex 90), spark discharge generated soot, anatase TiO₂, and SiO₂ induced catecholamine-mediated dose dependent increases in heart rate and dysrhythmias in Langendorff heart model systems³³¹ Human wood smoke exposure increases levels of serum amyloid A (a cardiovascular risk factor) and factor VIII in plasma¹⁵ Inhaled TiO₂ nanoparticles impair rat coronary arteriole endothelium-dependent vasoreactivity and relaxation, likely due to microvascular ROS¹⁷³

Intravascularly, nanoparticle characteristics and concentration determine leukocyte and immune stimulation (detailed in a later section), erythrocyte effects, thrombogenesis, endothelial dysfunction, and atherogenesis. Dendrimers can adversely alter human erythrocyte morphology, induce clustering, and provoke significant hemolysis.^{72,77} Dendrimer generation, concentration, charge, exposure duration, and material type determine the extent to which this occurs. Intravenously provided diesel exhaust particles aggregate within erythrocytes, decreasing counts.²⁴³ Polycationic (but not neutral or anionic) water-soluble fullerene C₆₀ derivatives, surfactant stabilized poly (lactic coglycolic) acid (PLGA) nanoparticles, and polystyrene nanoparticles all induce significant hemolysis.^{29,155,210} Chitosan/pDNA and uncoated polymer nanoparticles both induce significant hemoagglutination.^{121,190}

Engineered and combustion-derived carbon nanoparticles (MWCNTs, SWCNTs, and mixed carbon nanoparticles) stimulated human platelet aggregation, activation of GPIIb/IIIa, and accelerated the rate of vascular thrombosis in rat carotid arteries.²⁸⁷ The effect on platelet aggregation was aspirin-resistant but was reduced by low affinity (P2Y₁₂) ADP receptor antagonism. Multiple metal nanoparticles (iron, copper, gold, cadmium sulfide) also induced dose-dependent platelet aggregation through the P2Y₁₂ ADP receptor; an effect was blocked by clopidogrel.⁶² Epidemiologic studies support an association between exposure to particulate matter of less than 10 microns and increased risk of deep venous thrombosis.⁹ Diesel exhaust particles (20–50 nm) and positively charged polystyrene nanoparticles cause rapid activation of circulating blood platelets and microcirculatory thrombi.^{240,242} Healthy volunteers exposed to concentrated ambient air particles increase fibrinogen levels.¹⁰⁷

Compared to larger particles, ultrafine particles produce larger atherosclerotic lesions, decrease the antiinflammatory effect of HDL, and induce oxidative stress in susceptible animal models.⁶ At doses which produced no significant pulmonary inflammatory changes, rats exposed to nano-TiO₂ aerosols display systemic impaired endothelium-dependent arteriolar dilation, outright constriction, and decreases in NO bioavailability by increasing local reactive oxidative and nitrosative species.²⁴⁷

Immune System. Nanoparticle interaction with the immune system is complex: depending on biophysiochemical properties, nanoparticles can stimulate, silence, or elude immune responses⁴⁰⁷ Most concerning is induction of chronic inflammation. Work in murine macrophage cells lines demonstrated that MWCNTs produced a cytotoxic response nearly identical to asbestos³³⁰ Commercially and academically available MWCNTs induced asbestoslike, length-dependent pathology in mice^{275,360} MWCNTs can reach the subpleura in mice after a single inhalation exposure to produce mononuclear cell aggregates and subpleural fibrosis²⁹⁸ On the other hand, immune suppression may also occur. Fullerene suppression of mast cell-mediated hypersensitivity reactions appears to proceed from endocytosis, endoplasmic reticulum accumulation, intracellular persistence, and the inhibition of calcium and ROS generation⁶⁴

Particle-specific interactions may yield cellular accumulation, antigen mediated-immune stimulation, inflammatory mediator release, or fibrous or granulomata formation. Mouse granulocyte-macrophage colony formation is now a standard testing methodology for assessing nanoparticle toxicity.⁷ Macrophages exposed to Fe-Co-Ni nanowires in vitro increased production of IFN- γ , IL-1 α , IL-4, and IL-10.³ Ultrafine carbon caused macrophages to release²²⁵ lipid mediators arachidonic acid, PGE₂, LTB₄, and 8-isoprostane.¹⁶ Subcutaneously implanted “hat-stacked” carbon nanofibers in rats generated fibrous connective tissue formation and macrophage recruitment and ingestion without inflammatory response (necrosis, degeneration, or neutrophil infiltration).⁴⁰⁰ Intratracheal exposure to nano-sized nickel and cobalt particles induced rat blood neutrophils to release reactive oxygen species and reactive nitrogen species.²²⁰ Human volunteer exposures to concentrated ambient particles (< 200 nm) increased inflammatory blood mediators.¹¹⁰ IV administration of ultrafine diesel exhaust particles promoted monocyte and granulocyte proliferation.²⁴³ Other cell lines can also be induced to release inflammatory mediators. SWCNTs induced human epidermal cells exposed to release interleukin-8. MWCNT

introduced in human neonatal epidermal keratinocytes increased IL-8 and IL-1 β release.³⁸²

Direct immune stimulation can also occur. Fullerenes can induce an IgG response capable of cross-reaction with other fullerenes.^{31,46} The degree of induced opsonization by various IgG and complement molecules is thought to explain part of the differences seen in blood clearance and tissue distribution of nanoparticles.²⁵⁹ Upon readministration, PEGylated liposomes have accelerated blood clearance due to IgM binding; this is inhibited by chemotherapeutics which inhibit B-cell proliferation.¹³⁵ In the absence of direct immune stimulation, carbon nanotubes can boost immune response as adjuvants.²⁶¹ Indeed, pharmaceutical nanoparticles show promises for eliciting polyclonal and monoclonal antibodies to nonimmunogenic haptens as diverse as herbicides, antibiotics, and vitamins.²⁰⁵

Liposome- and polymer-based therapeutic nanomedicines have been compromised by non-IgE mediated hypersensitivity reactions due to complement system activation which releases C3a and C5a anaphylatoxins.⁵ The drug solubilizer Cremophor E-L (polyethoxylated castor oil) forms micelles (8–25 nm) at concentrations above 60 μ g/mL and causes its occasionally severe immune reactions presumable due to complement activation. Carbon nanotubes can activate human complement via both classical and alternative pathways; C1 q binds directly to carbon nanotubes.³⁰² Surface density of coating materials can also alter complement consumption.⁴ Certain dendrimers may also strongly activate the complement system.²²⁶ MnFe₂O₄ magnetic nanoparticles (10-nm diameter) induce severe inflammatory reactions in mice.¹⁶⁹ Microcrystalline silica particles induced a strong Th1 response, whereas carbon black particles and polystyrene particles induced a mixed Th1:Th2 response.³⁶⁸ PLGA-based nanoparticles did not induce complement consumption, indicating that this action is nanoparticle specific.⁴⁴

Ocular System. The ocular system is of particular interest due to its immunological privilege and physiologic characteristics. Therapeutically, nanosuspensions show promise for extended release and decreased drug clearance from the cornea and diminished systemic drug exposure.^{114,283} In vitro studies have shown adverse effects. Silver nanoparticle block the proliferation and migration and inhibit cell survival of bovine retinal endothelial cells.¹⁴⁶ Water-soluble fullerene derivatives are phototoxic to human lens epithelial cells under visible light.³⁸⁰ Conversely graphene oxide nanosheets, even when intravitreally injected, did not demonstrate significant effects.³⁹⁵ Cerium oxide nanoparticles appear to offer a protective effect, scavenging reactive oxygen intermediates in rat retina cell culture.⁴⁷ In vivo confocal neuroimaging conclusively demonstrated negatively charged nanoparticle-rhodamine formulations injected into rat jugular vein crossed the blood-retinal barrier within 40 minutes.²⁸² Intravenously administered gold nanoparticles (20 nm) can bypass the blood-retinal barrier to distribute in all retinal layers within 24 hours.¹⁵⁶

Reproduction and Development. Reproductive effects of nanoparticles are incompletely characterized. One review concluded that nanoparticles can breach the blood-testis barrier and locate in the testes.²¹² Subsequent studies using inhaled fluorescent magnetic nanoparticles (50 nm) and injected gold nanoparticles confirmed testicular distribution and persistence.^{12,168} Chronic intratracheal administration of carbon black (14 and 56 nm) showed similar partial vacuolation of the seminiferous tubules and decreased daily sperm production.⁴⁰¹ Silver nanoparticles caused dose-dependent mitochondrial impairment and cytotoxicity in spermatogonia in vitro; aluminum nanoparticles caused apoptosis.³⁴ Gold nanoparticles can penetrate human sperm cells, resulting in fragmentation and dysmotility.³⁸³ Environmental exposure to relevant concentrations of ZnO, TiO₂, SiO₂ nanoparticles produced reproductive toxicity in nematodes, which was correlated with ROS production and attenuated with antioxidants (ascorbate and N-acetylcysteine).³⁸⁷

Female reproductive effects are less well described. Oral ZnO nanoparticles achieved lactation and placenta transport and resulted in increased post-implantation loss rate, decreased live births, and zinc accumulation in offspring liver and kidney.¹⁴¹ In perfused human placenta models, PEGylated gold nanoparticles (10–30 nm) were retained mainly in the trophoblastic cell layer and internalized by trophoblastic cells and did not cross in detectable amounts into the fetal circulation over 6 hours of evaluation.²³⁰ Aquatic studies have illustrated detrimental reproductive and developmental effects. *Daphnia magna* were unable to reproduce again after exposure during pregnancy to sub-lethal concentrations of water stable fullerenes. Less than 10% of daughter daphnids matured following maternal exposure.³⁴¹ Following exposure to silver nanoparticles (0.1 or 0.5 mg/L for 3 days), nematode offspring decreased by 70%; oxidative stress was the presumed toxicological mechanism.²⁹² In the animal model of organogenesis, medaka (rice fish) eggs easily took up 39.4-nm fluorescent particles and concentrated them in the yolk area and gallbladder during embryonic development.¹⁴⁹ Adults demonstrated diffuse uptake into reproductive organs as well as the brain, liver, intestine, gills, and kidney. Medaka fertilized eggs exposed to silver nanoparticles produced a variety of malformations including systemic edema, hemostasis, and vertebral, finfold, optic, and cardiac abnormalities over the range of concentrations tested (100–1000 μ g/L).³⁸⁸ Altered hormone levels and offspring sex ratios seen in some experimental models of nanoparticle exposure suggest endocrine disruption.^{195,233}

Bioaccumulation and Persistence. Nanoparticles might accumulate in cells, tissues, or organs to achieve threshold toxicities at a later time than initial exposure. At the cellular level, nanocrystals can be passed to daughter cells upon

mammalian cell division^{117,208} Retained fluorescing QDs have been used experimentally to trace *Xenopus* cells from embryo to tadpole stage⁷⁶ As with different fine particles (fiberglass, rock wool, slag wool, asbestos), their biopersistent potential seems to underlie toxic effects¹²⁵ This knowledge drives the concern regarding preliminary studies demonstrating MWCNT persistence, inflammatory induction, and asbestoslike pathology^{225,275,298,338} Compared to sodium selenite, nano-selenium particles displayed hepatic hyperaccumulation and persistence in fish models, with associated oxidative stress and toxicity¹⁸¹ Similarly, uptake, bioconcentration, and alimentary toxicity of TiO₂ nanoparticles were demonstrated in crustaceans⁵⁹ Their transmission and bioaccumulation (by a factor of over 100% in certain species) up the food chain was also apparent³⁹⁹ Nanocrystalline C₆₀ had a greater propensity to accumulate in *D. magna* fetuses due to their higher lipid fraction (including the egg sac yolk) and correlated with higher mortality³⁴¹ Even short-term oral exposure may lead to reticuloendothelial accumulation in some animal models³⁴³

While desirable for chemotherapeutic applications, prolonged periods of persistence could allow leaching and toxicity of initially protected materials.³⁷⁷ Bone marrow deposition of nanoparticles²⁷⁸ could allow for ongoing systemic exposure. Persistence in other compartments could also permit more extensive distribution (eg, translocation from lung tissue). Dextran-coated ultrasmall SPIO particles currently used in clinical trials are retained by human monocyte-macrophages for days.^{227,228} QDs persisted at least 4 months in mice, while those conjugated to bovine serum albumin or coated with mercaptoundecanoic acid underwent negligible elimination in rats.^{13,90} Due to intrinsic resistance to lysosomal degradation, inorganic or metal nanoparticles can have extremely low rates of excretion, resulting in long-term accumulation.³⁷⁷

ADMINISTRATIVE, REGULATORY, AND RESEARCH ISSUE

The 21st Century Nanotechnology Research and Development Act guides US nanotechnology policy.³⁶⁴ Elements include federal interagency coordination, establishment of national strategic plans for nanotechnology, and triennial review by the National Research Council; establishment of a public database for funded environmental, health, and safety (ENS), educational and societal dimensions, and nanomanufacturing projects; fiscal support for a Nanotechnology Coordination Office; mandates for research in environmental, health, and safety; development of nomenclature and engineered nanoscale standard reference materials standards; development of standards for detection, measurement, monitoring, sampling, and testing of engineered nanoscale materials for environmental, health, and safety impacts; and nanotechnology education. The National Nanotechnology Initiative (NNI) is composed of 15 federal agencies with administrative, funding, liaison, regulatory, and research roles, including the Department of Defense, National Science Foundation, Department of Education, National Institutes of Health, NIOSH, FDA, National Institute of Standards and Technology (NIST), Environmental Protection Agency (EPA), US Department of Agriculture, and others. In its congressionally mandated role to review federal nanotechnology research and development, the National Nanotechnology Advisory Panel provides ongoing recommendations for development of infrastructure, standards and metrics, and EHS risk analysis concurrent with applications research.²⁸¹ International regulatory frameworks continue to evolve.²⁵²

The detailed NNI strategy for EHS research recommends incorporation of many factors in conducting a nanotechnology risk assessment, including nanomaterials synthesis and use, nanomaterial lifecycle stages (from raw materials through disposal or recycling), transport, transformation, secondary contaminants, abiotic effects, environmental concentrations, exposure of environmental and biologic systems, internal dose, biologic response, and systemic environmental effects.^{335,359–361} Identified immediate priority needs included the development of nanomaterial detection methods, certified reference materials, standardized physiochemical assessments, and measurement tools, understanding generalizable toxicologic characteristics of nanomaterials in biologic systems, identification of environmental, occupational, and other population exposures and health surveillance, and evaluation of risk management approaches to nanomaterials.³³⁵

Standards

NIST is the coordinating agency for instrumentation, metrology, and analytical methods in the United States. Given the broad cross-disciplinary impact of nanomaterials, international standards are urgently required for nomenclature and terminology, measurements and metrics, reference nanoparticles, toxicity testing, and occupational guidelines. Where available, selected national and international standards relating to these areas are provided in [Table 129–2](#).

TABLE 129–2. Selected Nanotechnology Standards

Nomenclature and Terminology	
ASTM E2456 - 06(2012)	Standard terminology Relating to Nanotechnology
ISO/TS 27687:2008	Nanotechnologies – Terminology and Definitions for Nano-Objects – Nanoparticle, Nanofibre and Nanoplate
ISO/TR 11360:2010	Nanotechnologies, Methodology for the classification and categorization of nanomaterials
ISO/TS 80004-1:2010	Nanotechnologies – Vocabulary – Part 1: Core terms
ISO/TS 80004-4:2011	Nanotechnologies – Vocabulary – Part 4: Nanostructured materials
ISO/TS 80004-5:2011	Nanotechnologies – Vocabulary – Part 5: Nano/bio interface
ISO/TS 80004-7:2011	Nanotechnologies – Vocabulary – Part 7: Diagnostics and therapeutics for health care
Measurements and Metrics	
ASTM E2578 - 07(2012)	Standard Practice for Calculation of Mean Sizes/Diameters and Standard Deviations of Particle Size Distributions
ASTM E2490 - 09	Standard Guide for Measurement of Particle Size Distribution of Nanomaterials in Suspension by Photon Correlation Spectroscopy (PCS)
ASTM E2834 - 12	Standard Guide for Measurement of Particle Size Distribution of Nanomaterials in Suspension by Nanoparticle Tracking Analysis (NTA)
ASTM E2859 - 11	Standard Guide for Size Measurement of Nanoparticles Using Atomic Force Microscopy
ASTM E2865 - 12	Standard Guide for Measurement of Electrophoretic Mobility and Zeta Potential of Nanosized Biological Materials
Toxicity Testing and Risk Assessment	
ASTM E2524 - 08	Standard Test Method for Analysis of Hemolytic Properties of Nanoparticles
ASTM E2525 - 08	Standard Test Method for Evaluation of the Effect of Nanoparticulate Materials on the Formation of Mouse Granulocyte-Macrophage Colonies
ASTM E2526 - 08	Standard Test Method for Evaluation of Cytotoxicity of Nanoparticulate Materials in Porcine Kidney Cells and Human Hepatocarcinoma Cells
ISO 10808:2010	Nanotechnologies – Characterization of nanoparticles in inhalation exposure chambers for inhalation toxicity testing
ISO 29701:2010	Nanotechnologies – Endotoxin test on nanomaterial samples for in vitro systems – Limulus amoebocyte lysate (LAL) test
ISO/TR 13121:2011	Nanotechnologies – Nanomaterial risk evaluation
ISO/TR 13014:2012	Nanotechnologies – Guidance on physico-chemical characterization of engineered nanoscale materials for toxicologic assessment
Occupational Health and Safety	
ASTM E2535 - 07	Standard Guide for Handling Unbound Engineered Nanoscale Particles in Occupational Settings
ISO/TR 27628:2007	Workplace atmospheres – Ultrafine, nanoparticle and nano-structured aerosols – Inhalation exposure characterization and assessment
ISO/TS 12901-1:2012	Nanotechnologies – Occupational risk management applied to engineered nanomaterials – Part 1: Principles and approaches
ISO/TR 13329:2012	Nanomaterials – Preparation of material safety data sheet (MSDS)

ASTM = ASTM International, ISO = International Organization for Standardization. No endorsement is implied.

Food, Drug, and Device Safety. The FDA regulates food and color additives, drugs, biologics, devices, blood products, and cosmetics to ensure that they are “safe” and unadulterated. The FDA does not regulate “nanotechnology,” and has forgone even adopting a regulatory definition¹¹⁵ Rather, marketing authorization occurs on a product-by-product basis, with further variation for different product classes. While the FDA can require manufacturers to provide necessary information (eg, chemistry, manufacturing, active ingredients, pharmacological and toxicological results, and particle size) to support decisions regarding premarket approval, in evaluating the sponsor “claims,” the FDA may be unaware that nanotechnology is being used, particularly if no nano-related claims are supplied. In general, the FDA has treated nanomaterial ingredients no differently than bulk material ingredients or products. Guidance in draft form only has been provided for nanotechnology and nanomaterials issues in industry, cosmetics, food substances, and dietary supplements. Several countries have excluded engineered nanoparticles from food labeled “organic.”³⁵⁸

Occupational Health and Safety. NIOSH leads federal agencies in conducting research and providing guidance on the occupational safety and health implications and applications of nanotechnology²³⁸ NIOSH has released multiple reports to guide commercial and research entities, including “Approaches to Safe Nanotechnology,”²³⁶ “Filling the Knowledge Gaps for Safe Nanotechnology in the Workplace.”²³⁸ and “General Safe Practices for Working with Engineered Nanomaterials in Research Laboratories.”²³⁷ These identify potential health concerns (nanoparticle dose, deposition, reactivity, toxicity, translocation, and tumorigenicity) and safety issues (fire, explosion, oxidation, and catalytic potential). Recommendations included epidemiology, surveillance, and background nanoaerosol measurements, personnel exposure sampling and assessment, engineering controls with verification, implementation of risk management programs, and use of filters, respirators, and other proper personal protective equipment when necessary²³⁶ To address specific risks associated with carbon nanotubes and nanofibers, the Occupational Safety and Health Administration (OSHA) recommends that worker exposure not exceed 1.0 µg/m³ elemental carbon as an 8 hour time-weighted average (TWA), based on the NIOSH-proposed occupational recommended exposure limit (REL)²⁵¹ OSHA recommends that worker exposure to TiO₂ nanoscale

particles not exceed the NIOSH REL of 0.3 mg/m³, an order of magnitude less than the NIOSH REL of 2.4 mg/m³ for fine TiO₂ particles (> 100 nm²⁵¹). The REL for soluble silver compounds and silver metal dust is 0.01 mg/m³, an order of magnitude less than the threshold limit value (TLV) for metallic silver (0.1 mg/m³) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH). The general federal statute limiting “particulates not otherwise regulated” (PNOR) (also known as “inert or nuisance dusts”) to a respirable fraction of 15 million particles per cubic foot of air (5 mg/m³) would also apply include nanoparticles, although this is suggested to provide inadequate protection^{80,325}. NIOSH anticipates that properly fit, NIOSH-certified respirators in conjunction with respiratory control programs will protect workers from most inhaled nanoparticles^{236,238}. Other occupational professional guidance can be found in national and international guidelines and reviews^{234,256}.

Environmental Protection. The EPA is the coordinating federal agency for human nanomaterials environmental research. Nanomaterial applications for environmental remediation and water purification are particularly attractive, but require weighing against unintended consequences (eg, nanopollution³⁵⁸). Regulation of nanomaterials and the effects of nanotechnology may also come under the EPA’s broad authorities under the Clean Air Act (CAA), Pollution Prevention Act (PPA), Clean Water Act (CWA), Safe Drinking Water Act (SDWA), Federal Insecticides and Rodenticides Act (FIFRA), Comprehensive Environmental Response Compensation and Liability Act (CERCLA), National Environmental Policy Act (NEPA), Resource Conservation and Recovery Act (RCRA), and Toxic Substances Control Act (TSCA³⁵⁸). For example, the EPA determined that (nano) silver ion-generating washing machines marketed with bactericidal claims were subject to registration requirements under FIFRA, and extended the requirement to copper- and zinc-emitting devices and ion generators in swimming pools⁸³. Under FIFRA, it has fined corporations for making unsubstantiated antimicrobial claims with nano-coating technology³⁵⁷. Under TSCA, new nanomaterials such as carbon nanotubes have been regarded as “chemical substances” and subject to review.⁸⁴

The rapid evolution of the discipline will mandate constant updating and assessment of available knowledge. A selected list of organizational resources is provided in [Table 129–3](#).

SUMMARY

- Nanotechnology and nanotoxicology represent ever expanding disciplines.
- The special physiochemical properties of nanoparticles can yield nonintuitive biologic effects, which complicate toxicological assessments.
- Nanoparticle profiles are incomplete. While surrogate markers of toxicity are suggestive, human risk remains incompletely characterized.
- Appropriate research methodologies, in vitro and in vivo models, risk assessment, and workplace and environmental standards await further exploration and consensus.

N. DISASTER PREPAREDNESS

130 RISK ASSESSMENT AND RISK COMMUNICATION

Charles A. McKay

All health care professionals confront questions involving risk on a daily basis. In the area of toxicology, these questions may take many forms. An anxious parent with questions about a child's potentially toxic exposure, an urgent consultation for a critically ill patient in the emergency department or intensive care unit, a request to interpret a laboratory test, media requests for information about environmental public health issues, a response to a hazard-materials situation, and biopreparedness education all involve directed communication of information and recommendations. Toxicologists and Certified Specialists in Poison Information (CSPIs) must establish rapport and provide information, instructions, and when appropriate, reassurance, typically by telephone or in short face-to-face interactions. For CSPIs, attribution of the patient's complaints to one or more potential exposures and ascertaining the true reason or concern behind a call are also difficult given the limited information and time and lack of visual clues that are usually available during a clinical evaluation. All of these situations require a knowledgeable, compassionate, and well-reasoned response.

This chapter focuses on two particular components of this response: risk assessment and risk communication. These principles apply equally to individual calls to poison control centers, interactions with the public and medical professionals in educational outreaches, occupational and environmental exposure evaluations, and supportive roles with other public health agencies in bioterrorism preparedness, environmental public health tracking programs, and research.

RISK ASSESSMENT

In the context of this text, risk assessment is the process of determining the likelihood of toxicity for an individual or group after a perceived exposure to some substance, generally referred to as a xenobiotic. It involves determining the nature and extent of the exposure (ie, xenobiotic, dose, duration, route) and its specific clinical effects, defining an exposure pathway, and assessing the likelihood of effects from a given situation. A published body of knowledge can be applied to some components of risk characterization or assessment. An overview and a number of tools can be accessed through the Web sites of the US Environmental Protection Agency (EPA) and the Agency for Toxic Substance and Disease Registry (ATSDR) of the Centers for Disease Control and Prevention (CDC).^{1,9} However, any given risk assessment is often based on incomplete information. This may include such features as uncertainty regarding the exposure xenobiotic or mixture, whether there has been an actual exposure or just proximity to the xenobiotic (completion of an exposure pathway), lack of the exact dose, or unpredictable features such as host factors (underlying medical conditions or genetic polymorphisms) that could modify the response to a potential exposure. Unfortunately, those conducting a risk assessment are affected by their own biases and assumptions in the interpretation of their results, as are the people to whom a risk assessment is communicated. The emotional response to being "poisoned" makes evaluation and attribution even more difficult.

A good example of the practical difficulties involved in a risk assessment is evident from a published description of mass psychogenic illness.¹⁸ In this incident, many individuals at a school complained of odor-triggered symptoms that spread in a so-called "line of sight" transmission with no evident dose-response pattern. Extensive testing identified the possibility of potential sources of exposure, such as dry floor drain traps. However, no actual release was documented, nor was a scenario that would present significant harm identified. Yet symptoms recurred when people returned to the school. This is considered an example of psychogenic illness. The extent of investigation of these events can be profound, highlighting the difficulty in appropriately applying potentially unlimited laboratory technology to a situation. In addition, our ability to assess a "no-risk" situation is limited, as can be noted in the letters to the editor of the journal in which the article was published criticizing the methods or conclusions in this event and "subsequent and comparable" outbreaks.^{4,16,23}

The response of individuals to uncertainty correlates with their affinity for one component of the negative data paradigm—"the absence of evidence of harm" versus "evidence of absence of harm." Both of these positions should have at their core the continued evaluation of evidence as it becomes available, with subsequent refinement of a resulting risk assessment. Unfortunately, these potentially converging points on a spectrum of knowledge and research have been polarized in debate and policy as two opposing principles: the Kehoe Principle and the Precautionary Principle. The Kehoe Principle is best summarized as "prove something is harmful before excluding a product with known benefits because of concern about potential, unproven future adverse effects." A common example of the use of this principle is the

continued marketing of a xenobiotic after another member of the class has been removed because of safety issues. More intense scrutiny may be indicated, but a class-wide medication recall without evidence of some level of harm by an individual therapeutic drug is very rare. This principle has been misused in the past to minimize known risks attributable to environmental lead pollution to delay removal of lead additives from gasoline.²⁶ Critics of the Kehoe Principle have suggested that waiting for evidence of harm from a substance results in costly or irreparable damage.

The alternative position of the Precautionary Principle is often summarized as “where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason to postpone cost effective measures to prevent environmental degradation.”^{21,30} Critics of the Precautionary Principle often cite the lack of attention paid to the “cost” component of the principle, complaining that devotees stifle economic growth and prosperity with unfounded fears rather than reasoned consideration of known data. This principle is commonly extended to potentially harmful situations other than the environment. A common criticism of the Precautionary Principle is the degree to which alternative actions have been evaluated for safety. As an example, concern about thimerosal safety (as a vaccine preservative and source of ethylmercury exposure) in young children led many parents to forego childhood vaccinations. Vaccine manufacturers have removed the thimerosal preservative from most routine childhood vaccines. Although this process was accelerated by the theoretical—and, ultimately, unfounded—concerns regarding this source of mercury exposure in young children, the cost of delayed or omitted vaccination was a number of real and preventable infectious diseases that occurred, including hepatitis B.^{5,6,11}

Although the Kehoe and Precautionary Principles originated as policy approaches to public health issues, they underlie the automatic or subconscious biases that each individual brings to his or her own personal risk assessment or tolerance. The response to uncertain situations is derived from one’s framing of belief systems and assumptions about life, justice, and eternity.^{3,10,14} These underlying world views should be explicitly recognized and addressed in a formal risk assessment. Table 130–1 lists the components of a risk assessment.

TABLE 130–1. Components of Risk Assessment

Hazard Identification

Name and amount of suspected xenobiotic (or general use category if the xenobiotic is unknown)

Exposure Pathway

Proposed route of exposure

Consistency with the nature of the xenobiotic (eg, water-soluble liquid)

Modifying Factors

Environmental factors that would influence systemic availability of the xenobiotic

Patient characteristics (susceptibility or resistance factors), such as:

Chronic medical conditions

Possible xenobiotic–drug or other interactions

Genetic polymorphisms in hepatic or other metabolic pathways

Toxicity Assessment

Compare and contrast organ effects expected from the particular xenobiotic with existing symptoms

DIFFERENTIATING PUBLIC HEALTH FROM INDIVIDUAL RISK ASSESSMENT

It is difficult to translate public health risk assessment done for populations by entities such as the EPA to the individual level. Simplistically, the iterative process of adjusting known noncancer adverse exposure outcome limits in an animal model (eg, lowest observed adverse effect level {LOAEL} or no observed effect level {NOEL}) to a safe level of exposure for all humans (including so-called “sensitive subpopulations”) has been arbitrarily set at repetitive multiplicative factors of 10 for each of these extrapolations. These are called “uncertainty factors” and are used in the

absence of specific information about human exposure to identify a conservative human “safe dose.” This would be set at 0.001 times the animal model LOAEL, reflecting a 10-fold reduction in dose for extrapolation from LOAEL to NOEL, another 10-fold reduction for extrapolation from animal to human, and another 10-fold reduction for potentially “sensitive” human populations. These “uncertainty factors” are actually safety factors for the adverse effect of interest. When individuals exceed these limits, they remain protected by very robust safety factors, and are not—as it is often portrayed—exposing themselves to a defined harm. An example of this is the dietary guidelines (also known as “fish health advisories”) for fish consumption based on concern about exposure to methylmercury and polychlorinated biphenyls. These dietary recommendations are based on epidemiologic studies that suggest subtle neuropsychiatric abnormalities in maternal–fetal pairs (in at least some populations) from levels of fish consumption 10 to 100 times that of the “usual” American diet. Clinical mercury toxicity requires still higher levels of consumption. Although it seems reasonable (precautionary) for pregnant women to limit their intake of certain high mercury-containing fish species, it is inappropriate to avoid fish and the nutrients contained therein because of a misplaced fear of mercury exposure. Furthermore, these risk assessments do not apply to nonpregnant women, children, or men, although they are often generalized to all humans.²

The public health modeling concept for cancer health effects risk assessment is even more complex and often misunderstood. In this setting, modeling assumes a linear, no-threshold carcinogenic effect from exposure to a given xenobiotic. Cancer risks from exceedingly small exposures are extrapolated from data in cancer-prone animal models with exposures so large that they are only likely in the experimental setting. This experimental construct ignores the moderating impact of incremental dosing of small amounts over a protracted period of time, and potential metabolic and self-repair mechanisms in humans. The “acceptable risk” in this setting is then taken as “one excess cancer in a population of 1 million exposed individuals.” Although a limitation of this model is explicit in the statement that this estimate represents “a plausible upper bound estimate of risk at low dose where true risk may be lower, including zero,”¹² this important caveat is rarely communicated, resulting in the common response by individuals that “an extra cancer may be acceptable for you, but not when it is my child.”

As this brief review of the principles of regulatory approaches to noncancer and cancer effects demonstrates, risk assessment is often imprecise. Risk characterization for the individual should avoid unfamiliar statistical concepts, aiming instead to communicate the likelihood of significant risk for the exposure actually experienced. The CDC has codified this approach for a community using such escalating terms as “no public health concern,” “public health concern,” “public health threat,” and “immediate risk.” Although there is debate about the general use of these terms in isolation (without explicit explanations), a similar approach with an individual could summarize the risk assessment using the phrases “safe,” “no adverse effects are expected,” “may be of concern—we will need to do some follow-up testing,” and “this might be (or is) a problem—let’s do the following studies or treatments.”

RISK COMMUNICATION

Risk communication consists of an exchange of facts and opinions that allow an individual or a group to make an informed decision regarding a course of action or treatment. Practically, risk communication is a way of translating incomplete knowledge so that individuals can achieve informed decision-making. During a one-on-one interaction with a poisoned individual and his or her family or a caller to the poison center, there is a need to gain the fullest attention or cooperation of the individual. After this has occurred, the discussion is usually focused on the risks and benefits of various treatment options (eg, gastrointestinal decontamination) or possible diagnostic modalities (eg, observation versus neuroimaging versus antidote administration). The group dynamics of environmental exposure risk communication at a public meeting are very different. Federal agencies that interact with communities in “Superfund” sites (eg, the EPA and the ATSDR) have promulgated principles and practical recommendations for risk communication in this setting. [Table 130–2](#) summarizes general principles of risk communication.

TABLE 130–2. Principles of Risk Communication⁷ and Applicability to the Poison Center

<i>Principle</i>	<i>Applications</i>
Accept and involve the individual as a partner	The caller must be involved to obtain the best information possible
Plan carefully and evaluate your efforts	There is a very short time to establish rapport with the caller; do not increase the caller's anxiety by asking irrelevant questions or arguing Monitor your tone; ask for repetition of key information or recommendations
Listen to the individual's specific concerns	Why did the person call? Was it for information, treatment recommendations, or reassurance? Make sure the underlying reason has been addressed
Be honest, frank, and open	If there is uncertainty or there are unknowns, indicate that uncertainty while providing a workable plan
Work with other credible sources	Involve medical toxicology backup and other consultants, particularly for questions regarding chronic exposure or effects
Meet the needs of the media	If calls involve media notification or contact, make sure the critical information is stated frequently, provide a human context, and avoid sensationalism
Speak clearly and compassionately	Remember that the caller was concerned enough to initiate the contact; make sure the call is completed with a clear plan; provide follow-up appropriate to the situation

Although some of these recommendations are more applicable to longer-term deliberations and interactions, much of the individual communication done by the poison center and medical toxicologists succeeds or fails based on these same principles (Table 130–2). Lacking the opportunity for repeated interactions over time to identify and discuss assumptions and biases, toxicologists need to establish credibility, listen to concerns and empathetically respond, admit areas of insufficient knowledge, and commit to follow-up interactions to convey effectively a risk characterization for an individual based on the available knowledge and experience. The scientific terms, rationale, and any extrapolation from modeling (eg, animal data or case series) should be conveyed in an understandable manner to show that appropriate safety factors are incorporated into areas of uncertainty as a risk-diminishing step. The patient or audience should leave the interaction with a clear understanding of the difference between a short-term risk of symptoms that will resolve or result in serious illness and the degree of certainty about the potential for a long-term consequence.

An example of poor risk communication can be found in the immediate aftermath of the World Trade Center disaster in September 2001. The mass rescue and recovery response was largely voluntary and heroic; however, inadequate attention was paid to the importance of respiratory protection against the heavy particulate and alkaline dust in the early hours after the towers collapsed. The high incidence and persistence of cough and other respiratory symptoms in responders have been attributed to this exposure. Communication of the real risk of respiratory symptoms to early responders would have emphasized the critical importance of appropriate use of personal protective equipment. This would have been balanced against the time-limited possibility of saving lives of those potentially trapped in largely inaccessible locations. Since 2001, a proliferation of other associations to World Trade Center dust exposure (including low birthweight) are reported, which are of doubtful validity.³¹ Appropriate risk communication to people concerned about these reports should emphasize the important role of confounders, the investigational nature of the study hypothesis, and the lack of relevant risk to any given individual.

Effective risk communication must therefore address several questions. After the best information has been obtained about the identification of the xenobiotic and the nature of the exposure, the following must be conveyed:

- Likely **magnitude** of the risk: This includes information on the process by which the person would be exposed (ie, the exposure pathway), such as airborne inhalation or drinking water delivery via a contaminated plume in the ground water and dose–response, such as: “Does the reported exposure to a particular xenobiotic (amount and duration)

approach the exposure amounts reported to cause symptoms?”

- **Urgency** of the risk must also be conveyed along with practical recommendations for simple actions consistent with the level of urgency.
- The **applicability** of a risk characterization might also need to be addressed. Are the animal data applicable to humans? Is the exposure something of concern for an individual?
- **Uncertainties** of the risk assessment: This could include a “worst-case scenario” approach to unknown exposures or uncertainties in the quantity of an absorbed dose. The need for continued observation or follow-up for clinical changes would be expressed here. Individual risk tolerance may vary greatly. The same information may be interpreted differently by risk-averse versus risk-tolerant people. A variety of comparisons or communication techniques may be used to provide an adequate characterization of risk. It is important to remember that the public and even medical professionals have limited ability to understand and incorporate data that rely on numbers and statistics. This health numeracy limitation is even more prevalent than is limited health literacy ([Chap. 135](#)).¹⁵
- **Management options**: In addition to follow-up and repeated evaluations by a medical toxicologist, the range of choices, associated with their relative benefits or risks, should be presented to the individual or group of individuals. A summary recommendation or opinion from the presenter should emphasize specific steps people can take to decrease exposure or potential toxicity if indicated by the level of risk. This last step is important because uncertainty significantly impacts the ability of an individual to take appropriate action. People should not leave the meeting or interaction with the impression that “no one knows what is going on or what we should do.”

APPLICATION OF RISK ASSESSMENT AND COMMUNICATION PRINCIPLES TO TOXICOLOGY

Although it has long been recognized that many home-initiated poison center calls concern nontoxic or minimally toxic xenobiotics potentially ingested by children,²⁴ the frequent lack of documented ingestion raises the possibility of under-triage based on misplaced confidence that relies on prior experience. It is generally assumed that the sheer volume of calls provides some reassurance regarding the accuracy of our risk assessment of these xenobiotics, but we should remain cautious in our interpretation of poison center data^{5,17,27} ([Chap. 136](#)). Moreover, even calls about nontoxic xenobiotics require communication between the caller and CSPI beyond simple substance identification. The importance of risk assessment and communication principles can be seen in the joint position statement²² on the prehospital management of “minimally toxic substances” crafted by the American Association of Poison Control Centers (AAPCC), the American Academy of Clinical Toxicology (AACT), and the American College of Medical Toxicology (ACMT). According to the position statement, a CSPI can make a risk assessment that an exposure is benign or minimally toxic only if the following characteristics are true²²:

- “The information specialist has confidence in the accuracy of the history obtained and the ability to communicate effectively with the caller.”
- “The information specialist has confidence in the identity of the product(s) or substance(s) and a reasonable estimation of the maximum amount involved in the exposure.”
- “The risks of adverse reactions or expected effects are acceptable to both the information specialist and the caller based on available medical literature and clinical experience.”
- “The exposure does not require a health care referral because the worst potential effects are benign and self-limited.”

The position statement further notes that patient disposition decisions can be altered by many additional factors, including intent, environment, presence of symptoms (possibly unrelated to the xenobiotic in question), and ongoing review of current recommendations in the face of more data.²² These points emphasize both the dependence of the CSPI on information derived from the caller and his or her confidence in the level of comprehension of the caller. The caller should understand that his or her exposed child is safe; the conversation with the toxicology experts should alleviate concern as the nature of the assessment process is explained to whatever degree is necessitated by the caller’s risk tolerance.

In the case of a symptomatic patient or a hospital-or physician-initiated contact to a poison center or medical toxicologist, the caller should expect more than just xenobiotic-related information; he or she also expects knowledge and expertise that will provide reassurance or direction for improving the patient’s health status. However, merely relaying information regarding the diagnosis, course, and predicted outcome is insufficient. There is often another underlying reason for the call. This could be anxiety, uncertainty, or misinformation established by an individual’s previous experiences or knowledge base. A sense of guilt may underlie a parent’s call for an inadvertent exposure occurring when a child was unsupervised. A health care professional may have previously had significant difficulties in the management of a poisoned patient. If these issues are not addressed, then the caller may continue seeking reassurance by repeated calls to the poison control center or by seeking additional input from other sources, such as family, friends, primary physicians, other health care providers. Any variance in the information obtained from these sources may be construed as inconsistencies between supposed experts rather than differences in emphasis with regard to the same information, leading to further uncertainty for

the caller. Of further concern, the Internet has become a common source of second opinion for health care. Although many sites are useful, there is no quality control or filter to sort good information from bad or even harmful advice.¹³ Table 130–3 lists some barriers to effective risk assessment and communication.

TABLE 130–3. Factors That Affect Appropriate Risk Assessment and Effective Risk Communication

Nature of previous encounters with poison center or health care field
Lack of prior patient–health care professional relationship
Incomplete or inadequate response to a prior question
The provision of information contrary to “popular understanding” or media representation
Loss of credibility
Lack of appreciation of individual or cultural differences in the perception of risk or the applicability of data
Incomplete or limited comprehension of scientific or statistical principles

INTERPRETING PUBLIC HEALTH CONCERNS FOR THE INDIVIDUAL

CSPIs and medical toxicologists frequently encounter callers or individuals at community events or interact with the media regarding public health–related issues, such as heavy metal exposures involving mercury, lead, or arsenic or concerns about “toxic mold,” plasticizers, and other environmental xenobiotics. Often these people are concerned that their symptoms or future personal or family health may be adversely impacted by such exposures. Such supposed exposures are usually poorly documented, sometimes also driven by popular media descriptions or litigation, and the risk is virtually impossible to ascertain during a short telephone or personal interaction. In these situations, the individual is best served by referral to a primary care physician with toxicology consultation or directly to a medical toxicology clinic. The data and perceptions can be completely reviewed and a more appropriate risk assessment communicated in those settings. These interactions are very difficult because they are often emotionally and politically charged.²⁵

In general, the communication of and response to information depend on a preexisting world view and prevailing circumstances. The same possible outcome will be perceived as more or less severe depending on factors other than the nature of the outcome itself. Several authors have characterized the perceived tolerance to different risks, stratified by features such as familiarity and personal control^{10,30} (Table 130–4). The emotional response of individuals confronted with these risks is sometimes characterized as “outrage.” One communications specialist has posited that “risk = hazard + outrage.”²⁸ He characterizes situations in which there is a significant hazard but little outrage as requiring “precaution advocacy,” essentially informing the relevant parties of the need for more action or involvement to reduce risk. On the other end of the spectrum is a situation with little hazard but significant outrage, which requires “outrage management” to address fear or anger that is dissociated from the actual hazard posed by the situation. The greater the degree of familiarity with the particular exposure situation and the greater the voluntary nature of the exposure, the less fear or outrage will be expressed for a given adverse outcome, whether this is an appropriate response or not. Although not necessarily applicable to the initial “fight-or-flight” response to an emergency, these concepts are certainly applicable to the aftermath of these events. Of note, although risk communicators use analogies to place exposures into a context familiar to their audience, one must be careful to avoid equating voluntary and involuntary risk assumption or equating those exposures or risks assumed by one segment of the population unequally. An example of this is the use of a smoking risk analogy when talking to a nonsmoker.

TABLE 130–4. Factors That Alter the Acceptability of Perceived Risk¹⁰

<i>More Acceptable</i>	<i>Less Acceptable</i>
Natural	Human made
Associated with a trusted source	Not associated with a trusted source
Familiar	Unfamiliar
Voluntary	Involuntary
Potentially beneficial	Limited or absent potential benefit
Statistical (low harm likelihood)	Catastrophic (high harm likelihood)
Fairly distributed or shared by all	Unfairly distributed (“injustice”)
Affects adults	Affects children

Risk communication has become very important in the setting of preparedness for terrorism. Although a great deal of attention and money have been directed to improvement of public health infrastructure, reporting and surveillance

mechanisms, and response to perceived and actual terrorist acts, less attention has been directed to the process of communicating risk to the individual.^{8,20} Although some countries practice public health emergency drills regularly, the United States has concentrated on development of organizational structures and lines of authority, with attention to the importance of outcome-based exercises only recently emphasized.

Maintaining readiness for catastrophic terrorist events (or natural occurrences such as pandemic influenza or storm related flooding) should use the same risk assessment and communication techniques appropriate for other urgent public health matters. Unfortunately, many factors affect the characterization of risk other than the facts. The importance of presentation style, perception, or the role of the communicator's own biases is exemplified by these two composite articles describing the same events:

1. Unknown assailants have infiltrated the mail delivery system, resulting in severe illness and death of children, healthy adults, and elderly people throughout the country. The initial symptoms can be nonspecific but rapidly progress to death if treatment is not begun early. The medical community routinely fails to diagnose the conditions early, and the government has no system in place to detect this threat after it occurs. The long-ignored public health system is not prepared to deal with the huge burden of preventing illness in those who may have been or will be exposed. Anyone who receives regular mail may be at risk. Tens of thousands of our citizens are taking prophylactic antibiotics "just in case." If you receive any unusual packages or see collections of powder that do not have an obvious explanation, call the police. If you develop a fever, cough, chest pain, or unusual rash, which may not be painful, seek medical attention at once. Tune in to your local news station for more information on this burgeoning threat to our nation's security.
2. A small number of individuals in isolated exposure settings have developed illnesses after bioterrorism events. Most people have survived these exposures, particularly with early and proper medical care. The government has developed a case definition, and medical experts have disseminated information to assist the medical community and public in the early recognition of symptoms and signs that are consistent with this exposure. Prophylactic treatment within days of exposure of those in high-risk professions, such as mail handlers at major postal sorting facilities, prevents illness. Unfortunately, there have been a large number of hoaxes and false alarms about possible terrorist events and a lot of understandable fear in the community about nonspecific symptoms. For more information, contact your local health department or use the CDC Web site: <http://www.bt.cdc.gov/agent/anthrax/needtoknow.asp>.

Both of these paragraphs describe the 2001 anthrax bioterrorism events within the United States, during which a total of 22 people become ill, of whom five died from anthrax exposure. The first communication suggests that everyone is at risk and the situation is dire; the communication in the second paragraph is that the risk is isolated (a single individual died who was not in what was recognized as an at-risk setting from the seven identified mailings) and there is a plan and process being developed to respond to the threat. Whereas the first is sensationalistic, imparting a helpless victim role to the reader, the second provides a framework in which to assess one's personal risk and access to sources of reliable information. Both types of reports were prevalent after the 2001 anthrax attacks. Which report seems more complete, accurate, or useful is determined by the assumptions and perspectives of the reader in addition to the message the author wishes to deliver or response desired. Some would say that communicating a high degree of risk is important to gain the attention of the reader and to ensure that no one ignores a warning. However, the lack of a risk perspective prevents the reader from placing this information in context with the myriad other risk communication messages conveyed on a daily basis. In general, risk communication messages that do not provide a context or comparison to generally familiar activities or risks are more prone to misinterpretation or misapplication. As biopreparedness moves from public health infrastructure development and surveillance improvement to planning and response drills, appropriate message development and risk communication to the public need to be emphasized.

SUMMARY

- High quality risk assessment and effective risk communication are the hallmarks of a successful interaction between the public and poison centers and between a toxicologist and an individual patient, the media, or the public health community.
- Adherence to general principles includes obtaining the best information possible regarding potential exposures and conveying in an understandable fashion a risk characterization of the hazard, likelihood of a completed exposure pathway (thus, the likelihood of an actual exposure), possible health effects, and treatment options.
- It is important to clarify the difference between public health standards and individual exposure risks, with an understanding of the many psychosocial issues that influence perception.
- Information should be provided in a context that allows the individual to prioritize his or her response based on a factual and balanced presentation with respect to his or her health literacy and health numeracy.

131 Hazardous Materials Incident Response

Bradley J. Kaufman

A hazardous material (hazmat) can be any xenobiotic (solid, liquid, or gas) with the potential to harm. Typically, we are most concerned about xenobiotics that can harm people, although a hazardous material may also harm other living organisms, the environment, or property. Outside of the United States, hazardous materials are often referred to as dangerous goods.

A “hazmat incident” implies that there was an unplanned or uncontrolled release of, or exposure to, a hazardous material. These terms are also used interchangeably; here we will use hazardous materials. Although there are no specific requirements for an event to be considered a hazardous materials incident, typically there must be the potential for many people or a large area to be affected; otherwise, all toxicologic exposures would fall into this category. Therefore, a hazardous materials incident falls within the larger disaster management framework within a community.

Hazardous materials include chemical, biologic, and radiologic xenobiotics. In fact, a single event could provide exposure to multiple xenobiotics. Complicating matters, the incident response required for chemical, biologic, or radiologic xenobiotics may differ substantially depending on many factors. For instance, an envelope containing a white powder suspicious for containing anthrax spores that is opened in an office might require decontamination of the exposed people and environment. However, the release of the same anthrax spores surreptitiously at multiple sites may not be recognized until days later because of the delayed onset of symptoms. Certainly, a very different emergency response would be required. Emergency managers and health care professionals must consider all possibilities and adjust the incident response based on the specific xenobiotics involved, the route of the exposure and other variables such as time. This chapter discusses the basic principles used for a confined and quickly identifiable hazardous materials incident.

In general, a hazardous materials incident response focuses on the care of patients exposed to xenobiotics in the prehospital setting, prepares for multiple casualties, and emphasizes patient decontamination while at the same time trying to prevent exposure and contamination of first responders and health care professionals.

Every emergency response has the potential to involve hazardous materials and therefore first responders must always appreciate this possibility. A simple motor vehicle collision often releases gasoline into the environment. A victim pulled from a burning building may have carbon monoxide poisoning. A terrorist may contaminate an explosive device with radioactive material (eg, dirty bomb). The early identification that an event involves a hazardous material will allow for better patient care.

DISASTER MANAGEMENT AND RESPONSE

Preparedness requires the planning of actions to be taken when a disaster occurs, as well as the practicing with mock exercises of these actions. Preplanning is critical to limit damage from an event, and numerous such hazardous materials incident response plans exist. The recovery phase occurs after the immediate needs and threats to human life are addressed in the response phase and entail the restoration of property, infrastructure, and the environment.

The response phase includes the mobilization of appropriate resources and the coordinated management of the incident. A hazardous materials incident response must include the containment of the xenobiotic followed by neutralization, removal, or both. Typically, such a response includes multiple trained professionals from various agencies, often including the emergency medical services (EMS), fire departments, police departments, environmental protection agencies, and other first responder emergency services personnel. In fact, major hazardous materials events, especially those considered purposeful or the result of a terrorist act, may have responders from multiple federal, state, and local agencies, each with equipment and vehicles, and hundreds of personnel at the scene. These events can be chaotic until control and coordination are achieved.

Disaster management has four phases: planning, response, mitigation, and recovery. Mitigation measures are plans and efforts that attempt to prevent or reduce the effects of a potential hazard from becoming a disaster or minimizing the effects of a disaster if it has already occurred. One example of a mitigation measure is to use a secure container to prevent leakage of a chemical that is to be stored.

Initial disaster management is provided by local resources and agencies with progressive escalation to county, state, and federal agencies as necessary. The US Federal Emergency Management Agency (FEMA) within the US Department of

Homeland Security is the lead federal agency for emergency management in the United States.

Medical professionals are a necessary part of all hazardous materials incident responses because patient assessment and treatment are typically the highest priority. However, as with all mass casualty events, physicians, and other health care professionals, even those highly trained in emergency medicine, toxicology, or hazardous materials response, must not respond to the location of the event unless they are part of a planned response team that has been requested to respond to the incident. Unsolicited medical personnel at the scene of a hazardous materials incident, although well intentioned, may actually harm the coordinated response and interfere with lifesaving efforts.

Limiting the loss of life is dependent on all responding agencies and personnel working efficiently and effectively together. The coordination of federal, state, and local governments is mandated by a National Incident Management System (NIMS).¹⁰ Interoperability and compatibility among on-scene assets are dictated by the Incident Command System (ICS), which consists of an organizational hierarchy and defines the necessary management components of the overall incident, including mechanisms necessary for controlling personnel, operations, and communications.

The request for mobilization, management, and utilization of volunteer medical personnel at the scene of a disaster should be planned for in advance for those events that might benefit from these resources.³⁰ Unsolicited medical professionals lack the communications equipment necessary to work within a multiagency coordinated operation. They often function outside the organized ICS. They may lack or be unaware of the necessary personal protective equipment (PPE). The medical treatments they provide may lack the oversight and protections required for the provision of medical care. These environments are, by definition, hazardous, and freelance medical personnel may in turn become patients themselves, thereby adding to the burden of on scene rescuers. Furthermore, although a patient affected by a specific hazardous material may have the same physical findings and treatment indications whether at the hazardous materials scene or at the hospital and although the same toxicologic principles apply, these differences in location often require variation in the medical decisions made and the actual care provided. Typically, disaster plans incorporate the utilization of local medical assets such as hospitals and clinics. Therefore, communities are best served if medical providers respond to their respective institutions during an incident.

RESPONSE COMPONENTS

After the release of a hazardous material, there must be a notification to emergency response personnel. Typically, someone witnesses the incident itself, such as a motor vehicle collision in which a tanker trailer is breached, or some resultant effects of the release, such as a fire, and the individual then activates the emergency response system by calling 9-1-1. Alternatively, an established detector may activate an emergency response to a hazardous materials incident even before there are easily observable results of the release.

The first responders may not be aware that an incident is hazardous materials related when responding. For instance, they may be assigned to respond to an unconscious patient, unaware that the cause of the medical emergency was a chemical exposure. Although every emergency response cannot be assumed to have a hazardous materials etiology, emergency responders must always remain vigilant for such situations.

Extensive knowledge, training, and judgment are required for all emergency personnel who respond to hazardous materials incidents. There are some basic paradigms followed for a hazardous materials response. Personnel should approach the scene from uphill and upwind if possible. They should not rush in to try to help patients because the rescuer may become an additional victim if exposed. It is important to establish a perimeter to secure the scene while evacuating those not contaminated, thereby preventing additional people from being exposed or contaminated. The identification of material, establishment of containment or safety zones, wearing of PPE, decontamination, and medical management of patients are discussed later. Other considerations include hazardous materials resources available, the need for escalation to other emergency response agencies, weather conditions, terrain, confinement of the release, intentionality, and the need for rapid rescue and evacuation of casualties.

Identification of Hazardous Materials

If the identity of the xenobiotic(s) is known before arrival at the scene, then research can begin while the responders are still en route with reviews of the physical, chemical, and toxicologic properties of the xenobiotic. If the xenobiotic is not known before arrival at the scene, then efforts to obtain this information should begin as soon as safely possible.

The identification of the specific xenobiotic(s) involved is of highest priority because many of the response components depend on the properties and potential health effects of the xenobiotic itself. Whether the incident involves a transportation element such as a rail car or road trailer or is at a fixed location such as a factory or medical facility, all available information must be used toward material identification, including placards, container labels, shipping documents, material safety data sheets (MSDS), detector devices, knowledgeable persons at the scene, patient signs and symptoms, and even odors at the scene such as the rotten egg smell of hydrogen sulfide.

Because many hazardous materials are transported via rail car or road trailer, emergency response personnel must

always maintain a high index of suspicion when responding to a transportation incident. In the United States, first responders are required to be familiar with the use of the Emergency Response Guidebook, which is an aid for quickly identifying the hazards of the material(s) involved in a transportation incident.⁴⁴

Hazardous materials may be categorized in various ways, often grouped by their harm-causing property. For instance, hazardous materials may be radioactive, flammable, explosive, asphyxiating, pathogenic, and biohazardous.

The xenobiotics most commonly encountered at hazardous materials incidents vary from one locale to another and are predominately determined by the major industries in a particular area.^{47,48} For example, pesticides are the most commonly encountered class of hazardous materials in Fresno County, California, whose major industry is agribusiness.⁴⁸ Although most hazardous materials incidents involve only one hazardous material, more than one hazardous material may be encountered at a given incident. One study described 107 hazardous materials incidents involving a total of 156 materials.⁴⁸

The vast majority of consequential hazardous materials incidents are caused by gases, vapors, or aerosols. In one study, four of the five most commonly encountered individual chemicals were ammonia, phosphine, sulfur oxides, and hydrogen sulfide.⁹ The important implication for decontamination is that gases do not usually contaminate people secondarily because they do not adhere to patients. Therefore, patients exposed only to gases generally do not require skin decontamination to prevent secondary contamination, and much greater efficiency is possible in patient care at gas, vapor, and liquid hazardous materials incidents. Inhalation is the most common route of exposure at hazardous materials incidents and was the route of exposure at 73% of the hazardous materials incidents, accounting for 76% of the exposed patients described in one study.^{8,9}

Because the number of hazardous materials is so large, it is efficient to group hazardous materials according to their toxicological characteristics. Various classification systems have been devised. The International Hazard Classification System (IHCS) is the most commonly used system (Table 131-1).^{44,47} Individual hazardous materials studies commonly use their own classification systems, emphasizing the toxicodynamic effects of hazardous materials such as systemic asphyxiants or highlighting individual chemicals such as ammonia or chlorine or general classes of chemicals such as acids, bases, or volatile organic compounds.^{8,9}

TABLE 131-1. International Hazard Classification System

Class 1: Explosives

- Division 1.1: Mass explosion hazard
- Division 1.2: Projection hazard
- Division 1.3: Predominantly a fire hazard
- Division 1.4: No significant blast hazard
- Division 1.5: Very insensitive explosives
- Division 1.6: Extremely insensitive detonating articles

Class 2: Gases

- Division 2.1: Flammable gases
- Division 2.2: Nonflammable compressed gases
- Division 2.3: Poisonous gases
- Division 2.4: Corrosive gases (Canada)

Class 3: Flammable/combustible liquids

Class 4: Flammable solids

- Division 4.1: Flammable solid
- Division 4.2: Spontaneously combustible materials
- Division 4.3: Dangerous when wet materials

Class 5: Oxidizers and organic peroxides

- Division 5.1: Oxidizers
- Division 5.2: Organic peroxides

Class 6: Poisonous materials and infectious substances

- Division 6.1: Poison materials
- Division 6.2: Infectious substances

Class 7: Radioactive substances

Class 8: Corrosive materials

Class 9: Miscellaneous hazardous materials

Chemical Names and Numbers. Chemical compounds may be known by several names, including the chemical,

common, generic, or brand (proprietary) name^{5,6} A chemical may be the sole substance in a given hazardous material or one of several compounds in a mixture

The Chemical Abstracts Service (CAS) of the American Chemical Society numbers chemicals to overcome the confusion regarding multiple names for a single chemical. The CAS assigns a unique CAS registry number (CAS#) to atoms, molecules, and mixtures. For example, the CAS# of methanol is 67–56–1.^{35,36} These numbers provide a unique identification for chemicals and a means for crosschecking chemical names. Identifying a chemical by name and CAS# is critical because one must be as specific as possible about the hazardous material in question. Trade or brand names can be misleading. The MSDS describing a product usually lists the chemical name, the CAS#, and the brand name.²⁹

Vehicular Placarding: UN Numbers, NA Numbers, and PIN. Substances in each hazard class of the IHCS (Table 131–1) are assigned four-digit identification numbers, which are known as United Nations, North American, or Product Identification Numbers, and are displayed on characteristic vehicular placards. This system is used by the US Department of Transportation in the Emergency Response Guidebook⁴⁴ The IHCS assigns a chemical to a hazard class based on its most dangerous physical characteristic, such as explosiveness or flammability. Other potential hazards of a xenobiotic, such as its ability to cause cancer or birth defects, are not considered. This system provides very little guidance in treating poisonings caused by hazardous materials

National Fire Protection Association 704 System for Fixed Facility Placarding. Fixed facilities, such as hospitals and laboratories, use a placarding system that is different from the vehicular placarding system. The National Fire Protection Association (NFPA) 704 system is used at most fixed facilities³¹ The NFPA system uses a diamond-shaped sign that is divided into four color-coded quadrants: red, yellow, white, and blue. This system gives hazardous materials responders information about the flammability, reactivity, and health effects, as well as other information, such as the water reactivity, oxidizing activity, or radioactivity

The red quadrant on top indicates flammability; the blue quadrant on the left indicates health hazard; the yellow quadrant on the right indicates reactivity; and the white quadrant on the bottom is for other information, such as OXY for an oxidizing product, W for a product that has unusual reactivity with water, and the standard radioactive symbol for radioactive substances.

Numbers in the red, blue, and yellow quadrants indicate the degree of hazard: numbers range from 0, which is minimal, to 4, which is severe, and indicate specific levels of hazard.

Similar to all placarding systems, this one also has limitations. It does not name the specific hazardous substances in the facility and gives no information about the quantities or locations of the materials.

United Nations. Recognizing that the transport of chemicals often occurs internationally and that the labels and MSDS often have different information in different countries, the United Nations developed a chemical classification system in an attempt to harmonize an approach to classification and labeling. The Globally Harmonized System of Classification and Labelling of Chemicals classifies substances and mixtures by their health, environmental, and physical hazards

CHEMTREC is a service of the Chemical Manufacturers Association providing continuous essential chemical information with regard to shippers, products, and manufacturers. CHEMTREC is available at 800–424–9300 or at <http://www.chemtrec.org> at no charge, 24 hours a day. Details of an incident are relayed to the shipper's or manufacturer's 24 hour emergency contact, and they in turn are linked to hazardous materials incident responders. Technical data are available on handling the substance(s) involved, including the physical characteristics, transportation, and disposal.

A regional poison center is another valuable source of information. Other information sources include local and state health departments, the American Conference of Governmental and Industrial Hygienists, Occupational Safety and Health Administration (OSHA), National Institutes of Occupational Safety and Health (NIOSH), Agency for Toxic Substances and Disease Registry, and Centers for Disease Control and Prevention.^{1,2,3,35,36,38}

Exact identification is desirable but not always possible. Hazardous materials responders may be able to classify the hazardous material into one of several major toxicologic classes by identifying a hazardous materials toxidrome that allows them to reasonably treat the patients and protect themselves and others. For example, do patients have irritation of the mucous membranes and upper airway caused by a highly water-soluble irritant gas? Do the patients exhibit signs of asphyxia with major central nervous system (CNS) or cardiopulmonary signs and symptoms? Do patients exhibit signs of cholinergic excess caused by organic phosphorus compounds or carbamate poisoning? Do patients exhibit chemical burns compatible with corrosives? Do patients have the odor of solvents with signs of CNS depression and cardiac irritability compatible with exposure to hydrocarbons or halogenated hydrocarbons?

Also, even when the exact identity of the hazardous material is not known, what is usually known is the physical state of the material, that is, solid, liquid, or gas. Airborne xenobiotics potentially mean many more victims. Airborne xenobiotics include not only gases and vapors but also the liquid suspensions (fog, aerosols, and mists) and the solid suspensions (smoke, fumes, and dusts).

Exposure and Contamination

A person may have received an external exposure to hazardous materials and may be at risk for the resultant health

consequences even though he or she may not be contaminated by the hazardous materials. For instance, a person may be temporarily irradiated by an exposure to a radioactive source. After exposure, a hazardous material may remain on a victim (external) or within a victim (internal). For instance, if radioactive materials (usually in the form of dust particles) are on the body surface or clothing (ie, contamination has occurred), and the person will continue to have exposure until decontamination occurs.

Primary contamination is contamination of people or equipment caused by direct contact with the initial release of a hazardous material by direct contact at its source of release. Primary contamination may occur whether the hazardous material is a solid, a liquid, or a gas. Secondary contamination is contamination of health care personnel or equipment caused by direct contact with a patient or equipment covered with adherent solids or liquids that have been removed from the source of the hazardous material spill.

The state of matter will help health care professionals determine whether the hazardous material presents a significant risk of secondary contamination and whether decontamination of the skin and mucous membranes is necessary. Secondary contamination generally occurs only with solids or liquids. In general, patients or equipment covered with adherent solid or liquid hazardous materials, including chemical, biologic, or radiologic agents, should be decontaminated before transportation to prevent downstream contamination of health care professionals and equipment. An exception to the principles of limited need for cutaneous decontamination for those exposed to gas is a patient whose sweaty skin was exposed to a highly water-soluble irritant gas such as ammonia that dissolves in sweat to produce corrosive ammonium hydroxide. In this case, the primary purpose of decontamination is to prevent or treat the patient's chemical burns caused by the caustic action of aqueous ammonium hydroxide on perspiring skin rather than to prevent secondary contamination of rescuers. Aerosols are airborne xenobiotics that are not gases. Aerosols are suspensions of solids or liquids in air, such as solid dusts or liquid mists, that can cover victims with these adherent solids or liquids, which can effect secondary contamination. These patients require decontamination to prevent secondary contamination.

Emergency personnel and equipment can become contaminated at hazardous materials incidents.^{12,20,21,22,47,48,51} For example, in one study, contamination occurred to one ambulance that drove through a puddle of liquid organic phosphorus pesticides that had spilled from a crashed exterminator truck. This ambulance was responding to a call for a "motor vehicle crash."⁴⁸

Hazardous Materials Site Operations

Limiting dispersion of the hazardous material is critical to prevent further ill consequences. The physical state of a material determines how it will spread through the environment and gives clues to the potential route(s) of exposure for the material. Unless moved by physical means such as wind, ventilation systems, or people, solids will usually stay in one area. Solids can cause exposures by inhalation of dusts, by ingestion, or rarely by absorption through skin and mucous membranes. Solids that undergo sublimation, changing directly from a solid into a gas without passing through the liquid state, can give off vapors that may cause airborne exposure. Only two commonly encountered solids sublime, dry ice (CO₂) and naphthalene. A vapor is defined as a gaseous dispersion of the molecules of a substance that is normally a liquid or a solid at standard temperature and pressure (STP), that is, 32°F (0°C = 273°K) and 1 atm (760 torr = 760 mm Hg = 14.7 psi). Uncontained liquids will spread over surfaces and flow downhill. Liquids may evaporate, creating a vapor hazard.

The vapor pressure (VP) is useful to estimate whether enough of a solid or liquid will be released in the gaseous state to pose an inhalation risk. VP is defined essentially as the quantity of the gaseous state overlying an evaporating liquid or a subliming solid. The lower the VP, the less likely the xenobiotics will volatilize and generate a respirable gas. Conversely, the higher the VP of a chemical, the more likely it will volatilize or generate a respirable gas. Water has a VP of approximately 20 mm Hg at 70°F (21°C), and acetone has a VP of 250 mm Hg at the same temperature. Therefore, acetone evaporates more rapidly than water and poses more of an inhalation risk. Standard reference texts (eg, NIOSH Pocket Guide to Chemical Hazards Merck Index) list VPs for commonly encountered chemicals.^{35,36,44}

Hazardous Materials Scene Control Zones. Scene management is a fundamental feature at a hazardous materials incident. It is almost always necessary to isolate the scene, deny access to the public and the media, and limit access to emergency response personnel to prevent needless contamination. Three control zones are established around a scene and are described by "temperature," "color," or "explanatory terminology" [Table 131–2](#) and [Fig. 131–1](#)). NIOSH, the US Environmental Protection Agency (EPA), and most US prehospital and hospital health care professionals use the temperature terminology system³⁶

TABLE 131–2. Nomenclatures of the Hazardous Materials Control Zones

<i>Temperature Terminology System^a</i>	<i>Color Terminology System</i>	<i>Explanatory Terminology System</i>
Hot zone	Red zone	Exclusion or restricted zone
Warm zone	Yellow zone	Decontamination or contamination reduction zone
Cold zone	Green zone	Support zone

^aFrom the National Institutes of Occupational Safety and Health and the Environmental Protection Agency.

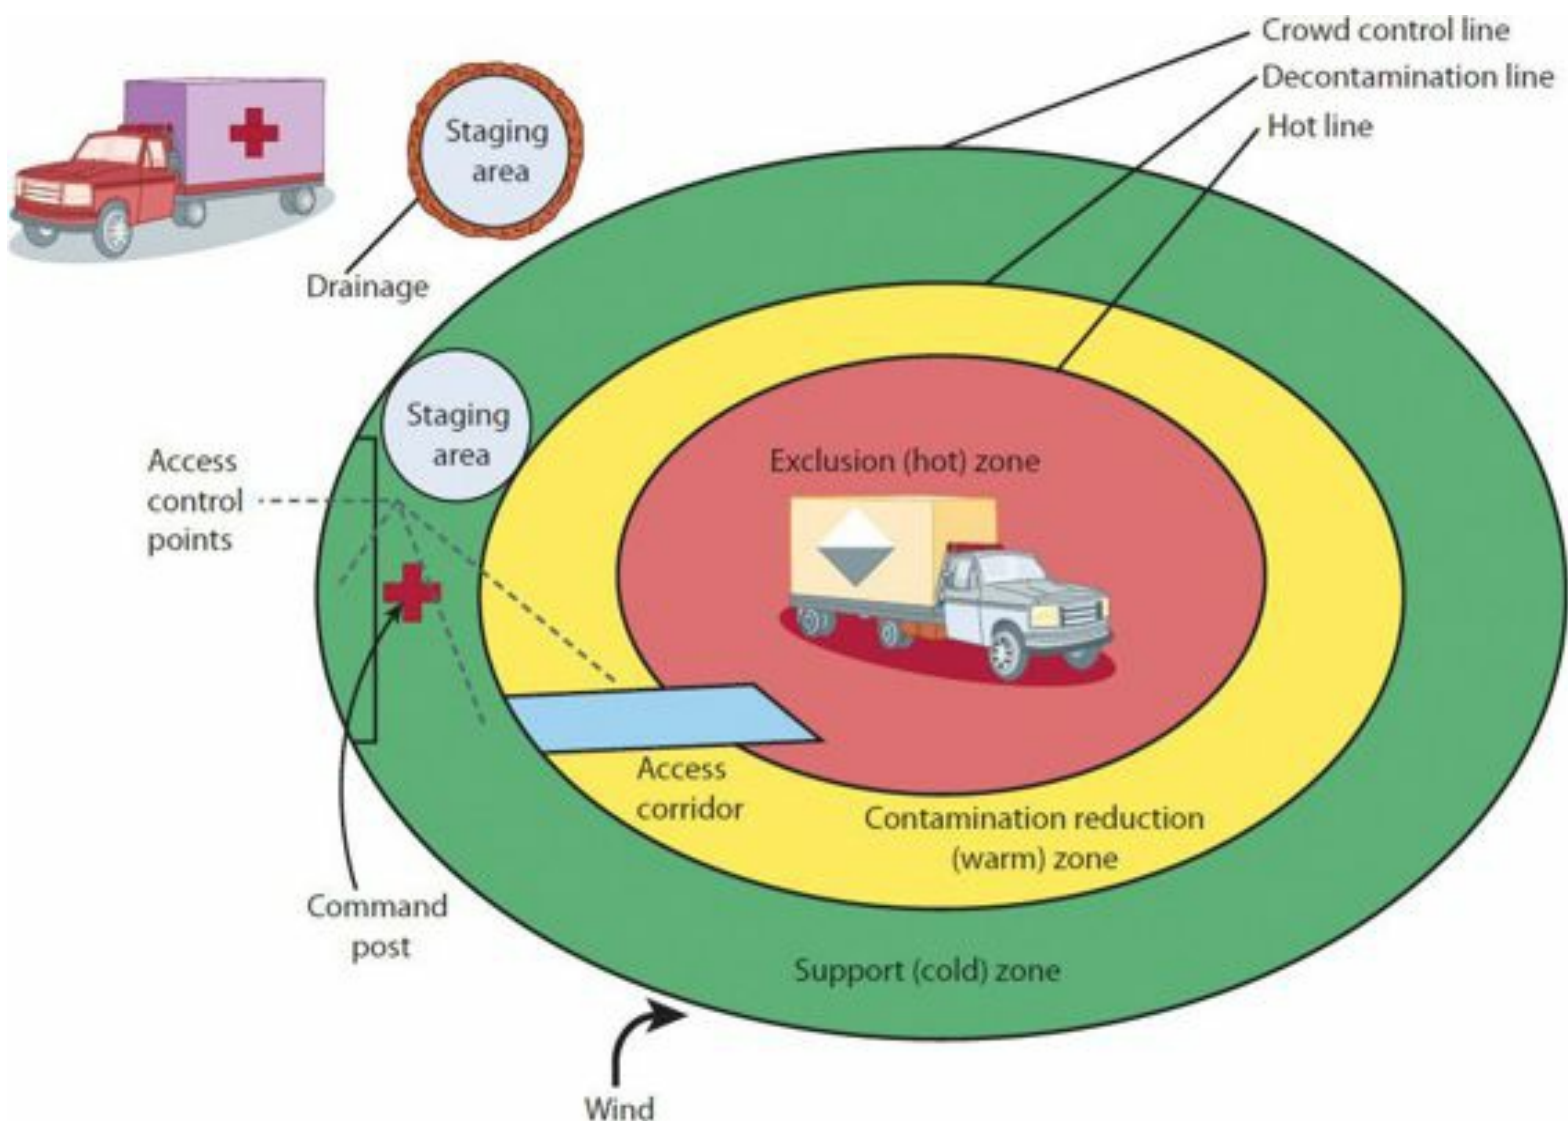

FIGURE 131-1. NIOSH/OSHA recommended hazardous materials control zones.

The hot zone is the area immediately surrounding a hazardous materials incident. It extends far enough to prevent the primary contamination of people and materials outside this zone. Primary contamination may occur to those who enter this zone. In general, evacuation—but no decontamination or patient care—is carried out in this zone, except for opening the airway and placing the patient on a backboard with spine precautions. This is because rescuers are generally hazardous materials technicians who wear level A or B suits that severely limit their visibility and dexterity. In specific situations, antidotes may be administered via autoinjectors as in the case of nerve agent antidotes.

The warm zone is the area surrounding the hot zone and contains the decontamination or access corridor, where victims and the hazardous materials entry team members and their equipment are decontaminated. It includes two control points for the access corridor. Many consider initiating therapy at this stage, particularly for chemical weapons, events where multiple casualties are involved.

The cold zone is the area beyond the warm zone. Contaminated victims and hazardous materials responders should be decontaminated before entering this area from the warm zone. Equipment and personnel are not expected to become contaminated in this zone. This is the area in which resources are assembled to support the hazardous materials emergency response. The incident command center is usually located in the cold zone, and there is greater ability to provide patient care there. Care provided in this zone includes the primary survey and resuscitation with management of airway (with

cervical spine control), breathing, circulation, disability, and exposure with evaluation for toxicity and trauma (ABCDE). Definitive care also includes antidotal treatment for specific poisonings.

Personal Protective Equipment

A critical goal of hazardous materials emergency responders is protecting themselves and the public. Safeguarding hazardous materials responders includes wearing appropriate PPE to prevent exposure to the hazard and prevent injury to the wearer from incorrect use of or malfunction of the PPE equipment.^{26,37}

PPE can create significant health hazards, including loss of cooling by evaporation, heat stress, physical stress, psychological stress, impaired vision, impaired mobility, and impaired communication. Because of these risks, individuals involved in hazardous materials emergency response must be trained regarding the appropriate use, decontamination, maintenance, and storage of PPE. This training includes instruction regarding the risk of permeation, penetration, and degradation of PPE. PPE with a self-contained breathing apparatus (SCBA) with a fixed supply of air significantly limits the amount of time the wearer can operate in the hot zone, usually about 20 minutes.

Levels of Protection. The EPA defines four levels of protection for PPE: levels A (greatest protection) through D (least protection). The different levels of PPE are designed to provide a choice of PPE, depending on the hazards at a specific hazardous materials incident ([Table 131–3](#))

TABLE 131–3. Personal Protective Equipment

Level ^a	Protects Skin and Eyes From			Protects Respiratory System From	
	Select Vapors and Aerosols	Gases, Vapors, and Aerosols	Oxygen-Deficient Atmospheres	Liquids and Solids	Gases and Vapors
D					
C	+			+	
B	+		+	+	+
A	+	+	+	+	+

^aLevel A is a self-contained breathing apparatus (SCBA) worn under a vapor-protective, fully encapsulated, airtight, chemical-resistant suit. Level B is a positive-pressure supplied-air respirator with an escape SCBA worn under a hooded, splash-protective, chemical-resistant suit. Level C is an air-purifying respirator worn with a hooded, splash-protective, chemical-resistant suit. Level D is regular work clothing (offers no protection).

Level A provides the highest level of both respiratory and skin (clothing) protection and provides vapor protection to the respiratory tract, mucous membranes, and skin. This level of PPE is airtight, fully encapsulating and the breathing apparatus must be worn under the suit.

Level B provides the highest level of respiratory protection and skin splash protection by using chemical-resistant clothing. It does not provide skin vapor protection but does provide respiratory tract vapor protection. Some hospitals have specially trained health care professionals who wear level B PPE when decontaminating patients presenting to the hospital. However, the majority of hospitals are training their frontline emergency department (ED) health care professionals to wear level C PPE when decontaminating contaminated patients who present to the hospital.

Level C protection should be used when the type of airborne xenobiotic is known, its concentration can be measured, the criteria for using air-purifying respirators are met, and skin and eye exposures are unlikely. Level C provides skin splash protection, the same as level B; however, level C has a lower level of respiratory protection than levels A and B.

Level D is basically a regular work uniform. It should not be worn when significant chemical respiratory or skin hazards exist. It provides no respiratory protection and minimal skin protection. Level D was specifically developed to show what not to wear for chemical protection.

Personal Protective Equipment Respiratory Protection. Personnel must be fit tested before using any respirator. A tiny space between the edge of the respirator and the face of the hazardous materials responder could permit exposure to an airborne hazard. Contact lenses cannot be worn with any respiratory protective equipment. Corrective eyeglass lenses must be mounted inside the face mask of the PPE. The only exception to these general rules are the use of hooded level C powered air purifying respirators (PAPRs) that do not require fit testing and allow individuals to wear their own eyeglasses within the hooded PAPR. This is the reason that most US hospitals prefer hooded PAPRs for their ED personnel who must decontaminate patients

Level A PPE mandates the use of a SCBA. A SCBA is composed of a face piece connected by a hose to a compressed

air source. An open-circuit, positive-pressure SCBA is used most often in emergency response and provides clean air from a cylinder to the face piece of the wearer, who exhales into the atmosphere. Thus, a higher air pressure is maintained inside the face piece than outside. This affords the SCBA wearer the highest level of protection against airborne hazards because any leakage will force air out of the face piece and not allow airborne hazards to enter against the higher pressure within the face piece. Disadvantages of the SCBA include its bulkiness and heaviness and a limited time period of respiratory protection because of the limited amount of air in the tank.

A supplied-air respirator (SAR) may be used in level B PPE and differs from SCBA in that air is supplied through a line that is connected to a source located away from the contaminated area. Only positive-pressure SARs are recommended for hazardous materials use. One major advantage of SARs over SCBA is that they allow an individual to work for a longer period. However, a hazardous materials worker must stay connected to the SAR and cannot leave the contaminated area by a different exit.

An air-purifying respirator (APR) may be used in level C PPE and allows breathing of ambient air after inhalation through a specific purifying canister or filter. There are three basic types of APRs: chemical cartridge, disposable, and powered air (PAPR). Although APRs afford the wearer increased mobility, they may be used only where there is sufficient oxygen in the ambient air. The chemical cartridges or canisters purify the air by filtration, adsorption, or absorption. Filters may also be used in combination with cartridges to provide increased protection from particulates such as asbestos. Powered devices reduce the work of breathing which can significantly limit an individual's performance while wearing PPE.

Decontamination

A major goal of the initial hazardous materials response is the decontamination of contaminated victims. Not only does decontamination reduce the health consequences for the victim (by reducing absorption or exposure time) but also prevents secondary contamination. Decontamination of equipment, the environment, and the entire area (ie, hot zone) may also be necessary but is secondary to the decontamination of victims.

An estimated 75% to 90% of contaminants may be removed simply by removing the victim's clothing and garments. Subsequent decontamination is most commonly accomplished by using water to copiously irrigate the skin of a victim, thereby physically washing off, diluting, or hydrolyzing the xenobiotic. However, the water solubility of a hazardous material must be considered to determine whether water alone is sufficient for skin decontamination or whether a detergent must also be used. The general rule regarding solubility is that "like dissolves like." In other words, a polar solvent, such as water, will dissolve polar substances such as salts. For example, the herbicide paraquat is actually a salt—paraquat dichloride—that is miscible in water. Therefore, if a patient's skin is contaminated with paraquat, copious water irrigation is sufficient for skin decontamination. A mild liquid detergent is acceptable but is not necessary. On the other hand, a nonpolar solvent, such as toluene, is not water soluble and is immiscible.^{35,36} Therefore, if a patient's skin is contaminated with toluene, water irrigation alone may be insufficient for decontamination, and a mild liquid detergent is also necessary.^{35,36} Furthermore, copious water may not be available at the site, thereby requiring rescuers to ration the supply and minimize irrigation using the least amount of water necessary. Some solid chemical contaminants may react with water and thereby cause an increased hazard if water used for decontamination. Such xenobiotics may be better removed mechanically by physically wiping it from the skin while avoiding smearing the xenobiotic or abrading the skin. Some contaminants may be chemically "inactivated" by applying another chemical, such as a 0.5% hypochlorite solution.

When performing decontamination, close attention should be paid to all exposed skin, particularly, the skin folds, axillae, genital area, and feet. Lukewarm water should be used with gentle water pressure to reduce the risk of hypothermia. Water should be applied systematically from head to toe while the patient's airway is protected.

Exposed, symptomatic eyes should be continuously irrigated with water throughout the patient contact, including transport, if possible. Remember to check for and remove contact lenses.

Removal of internal contamination is often much more problematic. In some cases, specific medications may be administered to enhance elimination or inactivate the hazardous material. For instance, Prussian blue can trap radioactive cesium in the intestine so that it can be eliminated from the body in the stool rather than be reabsorbed.

Scene Triage. Victim decontamination and movement from a scene requires an organized methodology for categorization of medical severity. The most common triage method used is the Simple Triage and Rapid Treatment system (START)⁴ although many others exist. This system follows a simple algorithm that allows for a color categorization based upon the victim's respirations, perfusion, and mental status: immediate (red), delayed (yellow), walking wounded/minor (green), and deceased/expectant (black). Victims may be initially triaged in the contaminated zone and then re-triaged after decontamination.

HAZARDOUS MATERIALS INCIDENT RESPONSE RULES AND STANDARDS

OSHA and the NFPA have developed rules and guidelines, respectively, regarding hazardous materials incident response.^{24,31–34,40,45} OSHA rules are mandated as law and must be followed.^{24,40,45} Meeting NFPA guidelines will ensure OSHA compliance.^{24,31,32,34,37,40}

The Superfund Amendments and Reauthorization Act of 1986 (SARA) required OSHA to develop and implement standards to protect employees responding to hazardous materials emergencies. This resulted in the Hazardous Waste Operations and Emergency Response standard, 29 CFR 1910.120, or HAZWOPER.⁴⁵

NFPA 471, Recommended Practice for Responding to Hazardous Materials Incidents, outlines the following tactical objectives: incident response planning, communication procedures, response levels, site safety, control zones, PPE, incident mitigation, decontamination, and medical monitoring.³²

NFPA 472, Standard on Professional Competence of Responders to Hazardous Materials Incidents, helps define the minimum skills, knowledge, and standards for training outlined in HAZWOPER for three types of responders.³³

Prehospital Hazardous Materials Emergency Response Team Composition, Organization, and Responsibilities

First Responder at the Awareness Level. First responders at the awareness level could be first on the scene at an emergency incident involving hazardous material. They are expected to recognize the presence of hazardous materials, protect themselves, secure the area, and call for better trained personnel. They must take a safe position and keep other people from entering the area. They must recognize that the level of mitigation exceeds their training and call for a hazardous materials response team. Most basic curricula of emergency medical technicians include this level of first responder training

First Responder at the Operational Level. These individuals are trained in all competencies of the awareness level and are additionally trained to protect nearby persons, the environment, and exposed property from the effects of hazardous materials releases. Operational level certified individuals are expected to assume a defensive posture, control the release from a safe distance, and keep the hazardous material from spreading. Operational level individuals are trained to perform absorption of liquids, containment of the spill, vapor suppression, and vapor dispersion. They do not operate within the hot zone

Hazardous Materials Technician. Hazardous materials technicians respond to hazardous materials releases, or potential releases, for the purpose of controlling the release. They are trained in the use of chemical-resistant suits, air-monitoring equipment, mitigation techniques, and the interpretation of physical properties of hazardous materials. Technicians are capable of containing an incident, making safe entry into a hazardous environment, determining the appropriate course of action, victim rescue, and cleaning up or neutralizing the incident to return the property to a safe and usable status, if possible. These individuals are trained to operate within the hot zone to mitigate the incident. This certification level includes knowledge of hazardous material chemistry, air-monitoring equipment, tools used within the hot zone, and more

Advanced Hazardous Materials Components

Advanced Hazardous Materials Providers. Paramedics should be trained in the recognition of signs and symptoms caused by exposure to hazardous materials and the delivery of antidotal therapy to victims of hazardous materials poisonings²⁴

The inclusion of such training into a hazardous materials response team is beneficial, not only for the needs of the public but also to protect hazardous materials technicians who make entry into hazardous atmospheres.²⁴ Ideally, hazardous materials technicians' entry into hazardous atmospheres should not be performed until appropriately trained paramedics are on the scene with resuscitative equipment in place, including a drug box containing essential antidotes for specific hazardous materials.²⁴

Patient Care Responsibilities of the Prehospital Decontamination Team and the Hazardous Materials Entry Team. Hazardous materials responders should identify the entry and exit areas by controlling points for the access corridor (decontamination corridor) from the hot zone, through the warm zone, to the cold zone (Fig. 131–1). This corridor should be upwind, uphill, and upstream from the hot zone, if possible. Hazardous materials technician entry team members should remove victims from the contaminated hot zone and deliver patients to the inner control point of the access (decontamination) corridor. Hazardous materials decontamination team members decontaminate patients in the decontamination (access) corridor of the contamination reduction (warm) zone^{11,14,18,19,24,27,28,42}

The primary responsibility of the prehospital hazardous materials medical sector is the protection of the hazardous materials entry team personnel. This is accomplished by researching and recording clinically pertinent information about the hazardous material, remaining available on scene for medical treatment, and assessing individuals before entry into and on exit from a hazardous environment.²⁴ Documentation of each assessment should be recorded on a prepared form and compared with the exclusion criteria defined by NFPA 471.^{24,32}

In some systems, the hazardous materials entry team may include specialized providers who have the ability to provide lifesaving patient care within the hot zone. The ability to perform triage or cardiopulmonary resuscitation or to provide any medical care is greatly limited by the PPE being worn. Therefore, only immediately lifesaving procedures should be considered, such as intubation/ventilation or antidote administration using an autoinjector.

Patient Care Responsibilities of Emergency Medical Services Providers at Hazardous Materials Incidents. EMS providers who are not part of the hazardous materials team should report to the incident staging area and await direction from the incident commander. They should approach the site from upwind, uphill, and upstream, if possible

EMS providers should remain in the cold zone until properly protected hazardous materials incident responders arrive, decontaminate, and deliver patients to them for further triage and treatment. Then EMS providers should evaluate each patient, triage as appropriate, and move the patient to the appropriate casualty collection point or rapidly transport to the hospital as resources allow. Exposed victims who are initially asymptomatic should continue to be observed and reassessed for the delayed development of symptoms, and the EMS provider should be prepared to upgrade the triage category for the patient. All EMS systems should have protocols in place that direct operations at hazardous materials scenes. Ideally, the EMS response matrix for such events includes the response of an EMS physician or contact with online medical control who will coordinate appropriate care with the regional poison center, toxicologists, and hospitals.

Transportation of patients from the hazardous materials incident is ultimately under the control of the incident commander but is usually delegated to the prehospital hazardous materials medical sector and EMS providers. In general, no victim with skin contamination should be transported from the hazardous materials site without being properly decontaminated. Before transportation, EMS should notify the receiving hospital of the number of victims being transported and their toxicologic history, patient assessments, and treatment rendered.

Hospital Responsibilities for Hazardous Materials Victims

Ideally, the local or regional ED physicians and personnel will receive advanced notification about a hazardous materials incident before any victims arrive at the hospital. This notification to the hospital should occur as early in the event as possible to allow for maximum “ramp-up” time. The notification should include, if known, information regarding the event, hazardous materials involved, number and condition of casualties to be transported to the hospital, as well as information regarding the decontamination completed. Assistance of a poison center and a toxicologist is generally recommended.

Victims may leave an incident scene and subsequently present to a hospital. The hospital must have a preestablished protocol by which hospital response teams will decontaminate patients who arrive at the hospital if they have not been previously decontaminated or if field decontamination is believed to be insufficient.^{7,15,16,17,23,25,39,41,43,46,49,50} Hazardous materials patients who require skin decontamination should be denied entry to the ED until they are decontaminated by an appropriately trained and equipped hazardous materials response team. The emergency physician will determine when the patient is safe to enter the ED after carefully assessing the risks and benefits to the decontaminated patient, the other patients in the ED, and the ED health care personnel.

SUMMARY

- Hazardous materials incident response is an integrated, interdisciplinary approach involving prehospital, hospital, poison center, and public health professionals.
- Most patients at hazardous materials incidents are exposed through inhalation of a gas, a solid, or a liquid aerosol.
- Prehospital and hospital health care professionals must use appropriate PPE when caring for patients who have not been decontaminated.
- Decontamination is critical to alter absorption for patients and to prevent secondary contamination of downstream health care professionals and equipment.
- The general principles of toxicology apply regardless of whether a patient is at a hazardous materials incident in a prehospital or hospital setting. Although patient care resources vary among these treatment settings, the fundamental principles of patient care remain the same. All patients should receive a primary survey and resuscitation, emphasizing airway, breathing, and circulation.

132 Chemical Weapons

Jeffrey R. Suchard

HISTORY AND EPIDEMIOLOGY

The first well documented intentional use of chemicals as weapons occurred in 423 B.C. when Spartans besieging Athenian cities burned pitch soaked wood and brimstone to produce sulfurous clouds.⁸² Chemical weapons were sporadically used, or their use considered, up through the nineteenth century.⁴⁶

Large-scale chemical warfare began in World War I when the Germans released chlorine near Ypres, Belgium, killing hundreds and forcing 15,000 troops to retreat.^{19,46} Both sides rapidly escalated the use of toxic gases, released from cylinders or by artillery shells, including various pulmonary irritants, lacrimators, arsenicals, and cyanides.

The Germans first used sulfur mustard in 1917, again near Ypres, and caused more than 20,000 deaths or injuries.⁴⁶ Unlike prior chemical weapons, mustard was persistent in the environment and vesicated the skin in addition to injuring the lungs and mucous membranes. The Allies soon responded in kind. Sulfur mustard was unequalled in its ability to incapacitate opponents.¹⁰ Injuries far outweighed fatalities, tying up manpower and resources to care for the wounded. By the end of the war, chemical weapons had caused more than 1.3 million casualties and approximately 90,000 deaths.¹⁹

Only one major chemical weapon event occurred during World War II. German planes bombed American ships carrying chemical munitions docked in the harbor of Bari, Italy, releasing the contents of 2000 mustard bombs and causing more than 600 Allied military and an unknown number of civilian casualties.^{10,46}

Germany began producing nerve agents just before World War II. Tabun was developed in 1936 by Gerhard Schrader when conducting insecticide research for IG Farbenindustrie,^{29,73} but was abandoned as an insecticide because of its overwhelming human toxicity. Sarin was synthesized in 1938, and named after its developers: Schrader, Ambrose, Rudringer, and Van der Linde.²⁹ Between 10,000 and 30,000 tons of tabun and 5 to 10 tons of sarin were produced during World War II. Soman was synthesized in 1944, but no large-scale production facilities were developed. When the Allies discovered these nerve agents at the end of the war, code names were designated based on the order of their development. Tabun was called GA (the letter G standing for German), sarin was GB, and soman was GD.²⁹

In 1952, the British synthesized an even more potent nerve agent while searching for a dichlorodiphenyltrichloroethane (DDT) replacement. This substance was given to the United States for military development, and was named VX. A VX leak killed 6000 sheep near a military base in Skull Valley, Utah in 1968.^{29,41,73} The Russians developed a similar nerve agent, variably referred to as VR or “Russian VX.”³⁷ The United States used defoliants and riot control agents in Vietnam and Laos. Iraq used sulfur mustard, tabun, and soman during its war with Iran in the 1980s, and may have also used cyanide against the Kurds.⁴⁶

Terrorist groups have also begun to employ chemical weapons. Sarin was released twice by the Aum Shinrikyo cult in Japan. The first release occurred in Matsumoto in 1994, killing seven and injuring more than 600.⁴⁸ A more highly publicized sarin attack occurred in the Tokyo subway system in 1995, killing 12 and resulting in more than 5000 persons seeking medical attention.⁷⁰ Cult members have also used VX in assassinations.⁴⁷ Chemical weapons may particularly appeal to terrorist groups, in that the technology and financial outlay required to produce them is much less than for nuclear weapons, although the potential morbidity, mortality, and societal impact remain high (Table 132–1).

TABLE 132–1. Unconventional Weapons: Definitions and Acronyms

Chemical warfare	Intentional use of weapons designed to kill, injure, or incapacitate on the basis of toxic or noxious chemical properties
Biologic warfare	Intentional use of microorganisms or xenobiotics derived from living organisms to cause death, disability, or damage in humans, animals, or plants
Terrorism	The unlawful use of force against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives
CW	Chemical warfare, or chemical weapon
BW	Biological warfare, or biological weapon
CBW	Chemical and/or biological warfare, or weapons
NBC	Nuclear, biological and/or chemical; usually in reference to weapons
CBRNE	Chemical, biological, radiological, nuclear, and explosive; usually in reference to weapons
WMD	Weapon of mass destruction; nuclear, radiologic, chemical, or biological weapon intended to produce mass casualties

Chemical weapons clearly fall within the purview of medical toxicology. Indeed, unlike the diverse xenobiotics widely studied by toxicologists that may incidentally cause poisonings, chemical weapons are specifically designed to kill, injure, or incapacitate. Some compounds generally considered nonlethal, such as tear gas and pepper spray, are therefore also considered chemical weapons. Biologic weapons share some characteristics with chemical weapons ([Table 132–2](#)) and are covered in [Chap. 133](#), although the issues common to both chemical and biologic weapons are discussed in this chapter.

TABLE 132–2. Chemical versus Biological Weapons: Comparison and Contrast²⁶

<i>Similarities</i>		
Xenobiotics most effectively dispersed in aerosol or vapor forms		
Delivery systems frequently similar		
Movement of xenobiotics highly subject to wind and weather conditions		
Appropriate personal protective equipment prevents illness		
<i>Differences</i>	<i>Chemical Weapons (CWs)</i>	<i>Biological Weapons (BW)</i>
Rate at which attack results in illness	Rapid usually minutes to hours	Delayed usually days to weeks
Identifying release	<i>Easier:</i> Rapid clinical effects Possible chemical odor Commercially available chemical detectors	<i>Harder:</i> Delayed clinical effects Lack of color, odor, or taste Limited development of real-time detectors
Xenobiotic persistence	Variable Liquids semipersistent to persistent Gases nonpersistent	Generally nonpersistent most BW xenobiotics degraded by sunlight, heat, desiccation (exception: anthrax spores)
Victim distribution	Near and downwind from release point	Victims may be widely dispersed by the time disease is apparent
First responders	EMTs, hazard materials teams, firefighters, law enforcement officers	Emergency physicians and nurses, primary care practitioners, infectious disease physicians, epidemiologists, public health officials (but may be same as CW if release is identified immediately)
Decontamination	Critically important in most cases	Not needed in delayed presentations; less important for acute exposures
Medical treatment	Chemical antidotes, supportive care	Vaccines, antibiotics, supportive care
Patient isolation	Unnecessary after adequate decontamination	Crucial for easily communicable diseases (eg, smallpox, pneumonic plague); however, many BW agents are not easily transmissible

This chapter focuses on the acute and long-term clinical effects of exposure to chemical weapons, their mechanisms of toxicity, and the medical treatment of individual casualties, based on published human case experience. There are many other potential subtopics related to chemical (and biologic) weapons that are not specifically reviewed here, including disaster incident command ([Chap. 131](#)), CBW agent detection, provision of medical care in a chemically contaminated environment, and the ever-growing body of evidence accumulated from in vitro and ex vivo models of chemical warfare agent poisoning.

GENERAL CONSIDERATIONS

Physical Properties

The term war gas is generally a misnomer. Sulfur mustard and nerve agents are liquids at normal temperatures and

pressures, and many riot-control agents are solids. These weapons are most efficiently dispersed as aerosols, which probably leads to the confusion with gases. Some chemical weapons (eg, chlorine, phosgene, hydrogen cyanide) are truly gases, and although they are generally considered obsolete for battlefield use, they might still be used as improvisational agents, especially in terrorist attacks.

Liquid chemical weapons have a certain degree of volatility and may evaporate into poisonous vapors. Volatility is inversely related to persistence, the tendency to remain in the environment. Persistent agents, such as mustard or VX, can contaminate an area for prolonged periods, denying the enemy free movement and use of contaminated material. The toxic hazard from semipersistent agents like sarin or nonpersistent agents like hydrogen cyanide dissipates more rapidly.

Aerosols, gases, and vapors are highly subject to local atmospheric conditions. Less dispersion occurs with atmospheric inversion layers and in the absence of wind, as typically occurs at night or in the early morning. Enclosed spaces also prevent wind dispersion and even simple dilution. Except for hydrogen cyanide, CW gases and vapors are all denser than air and will pool in low-lying areas.

As a practical example, consider the 1995 sarin release in the Tokyo subway system. The number of fatalities could have been much higher had it been effectively aerosolized instead of simply allowed to evaporate. Photos from the attack show severely affected or deceased victims in very close proximity to mildly affected, ambulatory individuals. Presumably, sarin concentrations decreased so rapidly as distance from the source increased that few victims were significantly contaminated. After removal from high-concentration areas, the victims' bodies posed less threat to bystanders because of dilution and improved ventilation. Even so, some health care professionals were secondarily exposed, as the victims were not disrobed prior to entering the hospitals. Up to 46% of hospital staff in areas with poor ventilation reported symptoms consistent with mild acute poisoning, although cholinesterase levels were not reported.^{52,53,56} About one-third of rescue workers in the 1994 Matsumoto sarin incident also developed mild toxicity. Rescuers arriving at the scene later were less likely to develop symptoms,⁴⁹ suggesting that the vapor had dissipated over time.

Preparation for CBW Incidents

A rational medical response to CBW events differs from the common response to isolated toxicologic incidents. Health care professionals must learn about these unconventional weapons and the expected “toxicodromes” that may occur.¹ In addition, health care professionals must protect themselves and their facilities first, or ultimately no one will receive care. New medicolegal and ethical considerations will arise in CBW mass-casualty events that otherwise infrequently occur. The greatest good for the greatest number of victims may preclude heroic interventions in a few critical patients. Charges of negligence may later arise regarding delays in treatment or failure to diagnose subtle signs of disease, even if such actions were unavoidable at the time. Even if physicians become well versed in the appropriate response to CBW incidents, the question remains as to how many will be willing to continue working in the presence of an actual public health disaster.³⁰

The responses to chemical and biologic weapons will also differ.²⁶ Chemical weapons, like conventional explosives, generally produce clinical effects within seconds to hours, making a “scene” or “hot zone” evident. The first responders for a chemical event will be fire and police authorities, hazmat teams, and emergency medical services. Patients will be brought to local health care facilities and the disease process, although perhaps not the specific etiology or diagnosis, will be recognized rapidly. With biologic weapons, the victims will not all present for care at the same time in the same place. First responders will be local and distant emergency departments (EDs) and primary care offices, highlighting the need for training in these specialties.

Recommendations for sustained health care facility domestic preparedness include improved training to promptly recognize CBW mass casualty events, efforts to protect health care professionals, and establishing decontamination and triage protocols.⁴⁰ Table 132–3 lists some specific recommendations. Several facets of the response to a CBW event are still being refined, such as the optimal choice of personal protective equipment, determining who needs decontamination and by what means, and what is to be done with wastewater produced by mass decontamination.^{36,40} On a tactical level, communication can be severely impaired by personal protective gear, which points out the need for loudspeakers or other forms of public address.^{40,81}

TABLE 132–3. Recommendations for Health Care Facility Response to Chemical and/or Biological Warfare or Weapons Incidents

- Immediate access to personal protective equipment for health care professionals
- Decontamination facilities that can be made operational with minimal delay
- Triage of victims into those able to decontaminate themselves (decreasing the workload for health care providers) and those requiring assistance
- Decontamination facilities permitting simultaneous use by multiple persons and providing some measure of visual privacy
- A brief sign-in process where patients are assigned numbers and given identically numbered plastic bags to contain and identify their clothing and valuables

- Provision of food, water, and psychological support for staff, who may be required to perform for extended periods
- Secondary triage to separate persons requiring immediate medical treatment from those with minor or no apparent injuries who are sent to a holding area for observation
- Providing victims with written information regarding the agent involved, potential short and long term effects, recommended treatment, stress reactions, and possible avenues for further assistance
- Careful handling of information released to the media to prevent conflicting or erroneous reports
- Instituting postexposure surveillance

Individual clinicians and hospitals caring for victims of known or suspected CBW incidents should contact their local department of health, which may in turn report the incident to outside agencies such as the US Federal Bureau of Investigation and the Centers for Disease Control and Prevention (Table 132–4).

Decontamination

Decontamination serves two functions: (1) to prevent further absorption and spread of a noxious substance on a given casualty, and (2) to prevent spread to other persons. Chemical weapons that are exclusively gases at normal temperatures and pressures such as chlorine, phosgene, or hydrogen cyanide only require removing the victim from the area of exposure. Isolated aerosol or vapor exposures, as from volatilized nerve agents or sulfur mustard, are also terminated by leaving the area and may require no skin decontamination of the victims.^{46,71} Japanese experience with sarin suggests that clothing should be removed from victims of nerve agent vapor exposure and placed in airtight receptacles, such as sealed plastic bags. Some of the secondary exposures to sarin were thought to have occurred as nerve agent that had condensed on the victims' clothing revaporized into the ambient air, and this caution probably holds true also for sulfur mustard vapor exposures.

Chemical weapons dispersed as liquids present the greatest need for decontamination. Because nerve agents are highly potent and have rapid onset of effects, some victims with significant dermal contamination may not survive to reach medical care.⁷¹ Liquid-contaminated clothing must be removed, and, if able, victims should remove their own clothing to prevent cross-contamination.

Decontamination should be done as soon as practicable, to prevent progression of disease, and should occur outside of health care facilities to prevent contamination of the working environment and secondary casualties. Decontamination near the incident scene would be ideal in terms of timeliness, although logistically this will not be possible in many situations. Field decontamination prior to transport will also help to avoid loss of vehicles from being contaminated and taken out of service. Evidence supports the likelihood that contaminated victims will present at health care facilities on their own, or be transported for care without decontamination.³⁶ In mass-casualty incidents, decontamination efforts may benefit from separating victims into those who can remove their own clothing and shower themselves with minimal direction and assistance, and the more seriously affected who will require full assistance. The degree of protective gear required by the decontamination personnel cannot be predicted in advance, and may be difficult to objectively determine at the time of the incident. Level C personal protective equipment may be sufficient for most hospital settings when the source is defined (eg, receiving and decontamination areas); however, if health care professionals begin to develop symptoms, then level B gear with supplied air would become necessary⁵⁴ (Chap. 131). When the source of the contamination is not yet known, level B gear should be used. Chemically contaminated victims presenting to a health care facility should, if possible, be denied entrance until decontaminated. Patients who have already entered a health care facility and are only later determined to be a contamination hazard present a more difficult problem. If the situation allows, such patients should be taken outside for

decontamination before returning, and the previous care area cordoned off until any remaining safety hazard has been assessed and eliminated. However, in a mass-casualty disaster, such efforts at remediation may not be practical.

Nerve agents are hydrolyzed and inactivated by solutions that release chlorine, such as household bleach, or solutions that are sufficiently alkaline. To avoid potential dermal and mucous membrane injury, a 1:10 dilution of household bleach in water (producing a 0.5% sodium hypochlorite solution) is recommended, not only for nerve agents, but also for sulfur mustard and many biologic agents.^{40,44,73} Alternatives include regular soap and water or copious water alone. Rapid washing is more important than the choice of cleaning solution because 15 to 20 minutes is necessary for hypochlorite solutions to inactivate chemical agents.⁴⁰ Care should be taken to clean the hair, intertriginous areas, axillae, and groin.⁷³

Decontamination after sulfur mustard exposure is more problematic than for nerve agents. First, it is more likely that significantly contaminated victims will survive to reach medical care, and they may remain asymptomatic for several hours. In addition, the biochemical damage becomes irreversible long before symptoms develop. Decontamination within 1 to 2 minutes is the only effective means of limiting tissue damage from mustard.⁷⁵ However, the actual means of mustard decontamination are identical to those for nerve agents. Victims must be disrobed and thoroughly showered. Dilute hypochlorite solutions (eg, 0.5% sodium hypochlorite, a 1:10 dilution of household bleach) are advocated to inactivate mustard, but copious water irrigation will also suffice.⁴⁶ Symptomatic victims of mustard exposure should still be decontaminated, although it is unlikely to benefit that particular individual it can prevent the spread of mustard to others.⁷⁵ Lewisite and phosgene oxime must also be decontaminated quickly, although they produce immediate symptoms, making it more likely that victims will present promptly when decontamination is most effective.

Water irrigation is generally recommended for riot control agent exposures because hypochlorite solutions may exacerbate skin lesions.⁴⁶ Inadequately decontaminated patients exposed to lacrimators can produce secondary cases among health care professionals, so any contaminated clothing should be removed and bagged.

Significant issues remain regarding decontamination measures. The number of people potentially requiring decontamination may easily outstrip capacity. Incidents with hundreds or thousands of victims may necessitate communal showers, selective decontamination, or both. Decontamination wastewater should ideally be contained and treated, but few facilities have the capability or funds to do this. However, wastewater may be a minor issue, since with large scale chemical weapons events the wastewater represents only a small percentage of the total environmental impact.⁴⁰

Risk of Exposure

The actual release of chemical or biologic weapons can be characterized as a low-probability, high-consequence event. Potential sources for civilian exposure include terrorist attacks, inadvertent releases from domestic stockpiles, direct military attacks, and industrial events. Terrorists may sabotage military or industrial stockpiles or directly attack the populace. Experience has shown that physicians are much more likely to encounter hoaxes,¹³ isolated cases,⁶² or limited incidents with a modest number of casualties.⁸⁰ Riot control agents are exceptions, in that treating riot control agent and pepper spray victims is a routine occurrence in many urban EDs.

Technical and organizational obstacles decrease the chance of major CBW terrorist events. Obtaining or producing chemical or biologic weapons, although simpler than for nuclear weapons, is only part of the process. Effective dissemination is difficult if the goal is to maximize casualties. Proper milling of biologics to produce stable, respirable aerosols requires technical sophistication probably only attainable with governmental research support. Low-technology attacks such as food contamination, poisoning of livestock, and enclosed-space weapons dispersal appear more likely to occur than attacks resulting in hundreds, thousands, or millions of casualties. Smaller attacks, or merely threatening use of chemical or biologic weapons, may be equally consequential from a terrorist's perspective if they exert comparable political influence with significant psychosocial impact.

The chemicals most likely to be used militarily appear to be sulfur mustard and the nerve agents. A "low-tech" terrorist attack could involve the release of toxic industrial chemicals, such as chlorine, phosgene, or ammonia gas as chemical "agents of opportunity."

Psychological Effects

Either the threat or the actual use of CBW agents presents unique psychologic stressors. Even among trained persons, a CBW-contaminated environment will produce high stress through the necessity of wearing protective gear, potential exposure to agents, high workload intensity, and interactions with the dead and dying. Disorders of mood, cognition, and behavior will be common among exposed or potentially exposed victims as a result of the uncertainty, fear, and panic that may accompany a CBW incident, even a hoax. The psychological casualties will probably outnumber victims requiring medical treatment. Civilians without training, including some health care professionals, are likely to confuse somatic symptoms with true exposure. Medical resources may easily be overwhelmed unless triage can identify those who will benefit most from appropriate counseling, education, and psychologic support. Psychiatrists and other disaster mental health personnel should be enlisted in plans to manage CBW incidents for their expertise in treating anxiety, fear, panic,

somatization, and grief.¹⁵

In Israel during the Gulf War, anxiety-related somatic reactions to missile attacks were reported in 18% to 38% of persons surveyed,¹¹ and more than 500 people sought medical attention in EDs for anxiety.⁵⁹ Among 5510 people seeking medical attention after the Tokyo subway sarin release, only about 25% were hospitalized.⁷⁰ Some of the “victims” presented days or even weeks after the incident, apparently feeling unwell and thinking they were exposed.^{53,57} Civilian survivors of chemical attacks in the 1980–1988 Iran–Iraq war report increased symptoms of depression, anxiety, and posttraumatic stress disorder compared to those exposed to low-intensity conventional warfare.²³ In one longitudinal study of American Persian Gulf War veterans, 4.6% reported their belief that they were exposed to CBW agents, despite the lack of any convincing evidence of deliberate exposures, nor of unintended exposure to any significant levels of chemical agents. Greater combat stress was associated with a higher incidence in belief in such exposures.⁷⁶ Another study reported a 64% incidence in belief of CBW agent exposure among Gulf War veterans.⁹ Reported indicators supporting these beliefs included receiving an alert, having physical symptoms, and being told to use protective gear. Belief in exposure to biologics correlated with having received an alert about chemicals, suggesting that CW alerts can spread misinformation and confusion among recipients.

Uncontrolled release of information may compound terror and increase psychologic casualties. Imagine the influx of patients resulting from a news report suggesting that anyone with dizziness or nausea be checked for nerve agent toxicity, or that fever and cough indicate infection with anthrax.

Israeli Experience during the 1990–1991 Gulf War

Israel is probably one of the best prepared countries for CBW disasters. In late 1990, the civilian population was supplied with rubber gas masks, atropine syringes, and Fuller’s earth decontamination powder.⁵⁹ Major Israeli hospitals conduct chemical practice drills every 3 to 5 years.⁸¹ These drills identify several key lessons, including designating specific hospitals for chemical casualties, blocking hospital access to a single guarded entrance to prevent internal contamination, and extending nurses’ authority to initiate treatment by established protocols. The Israeli plan provides two tiers of triage. The first triage occurs outside of the hospital by protected medical personnel who perform only life-saving interventions, such as intubation, hemorrhage control, and antidotal therapy. Patients are then decontaminated and enter the hospital. Afterward, patients are triaged again according to severity of illness into separate areas in which dedicated health care teams provide the appropriate interventions.^{64,81}

Thirty-nine ballistic missiles with conventional warheads were launched against Israel from Iraq in early 1991, with only six missiles causing direct casualties. Many more “injuries” resulted from CBW defensive measures and psychologic stress than from physical trauma. Out of 1060 injuries reported from EDs during this time period, 234 persons were directly wounded in explosions (most injuries were minor), and there were only two fatalities from trauma.^{32,59} More than 200 people presented for medical evaluation after self-injection of atropine, a few requiring admission to the hospital.^{3,32,59} About 540 people sought care for acute anxiety reactions. Some suffocated from improperly used gas masks, fell and injured themselves when rushing to rooms sealed against CBW agents, or were poisoned by carbon monoxide in these airtight rooms.^{32,59} Increased rates of myocardial infarction and cerebrovascular accidents were also observed.⁵⁹ A survey of hospital staff members found that only 42% would report for duty following a chemical weapon attack.⁶⁵

Special Populations

Pregnancy does not appear to be a significant factor in the treatment of women victims of chemical weapons. In the Tokyo subway sarin attack, five victims were identified at one hospital as being pregnant. These women were only mildly affected and were admitted for observation. All had healthy babies, the first one born 3 weeks after the incident.^{53,55,57} In Israel, no obstetric complications occurred among women wearing gas masks during labor and delivery.^{18,59}

Children differ substantially from adults with regard to chemical weapons effects and decontamination efforts. Children breathe at a lower elevation above the ground and at a higher rate than adults. Because nearly all chemical weapon gases and vapors are heavier than air, children will be exposed to higher concentrations than adults in the same exposure setting, and will likely exhibit symptoms earlier.^{5,61,86} Children may also be more susceptible to vesicants and nerve agents than adults with equivalent exposures.^{60,86} Children have thinner and more delicate skin, allowing for more systemic absorption and more rapid onset of injury with sulfur mustard. The blood–brain barrier of a child may also be less resistant than in adults and the activity of endogenous detoxifying enzymes, such as paraoxonase, is less, allowing for greater toxicity with nerve agents. Additionally, children with organic phosphorus compound poisoning less frequently exhibit a muscarinic toxic syndrome than adults, and often present with isolated central nervous system (CNS) depression.⁶⁰

The decontamination of children is another feature that requires an age-adjusted approach. Children have a larger surface area-to-mass ratio and may be more likely to carry a toxic or fatal dose of a chemical weapon on their skin. Most children will need assistance and supervision during decontamination procedures; keeping a mother or other adult guardian

with a child should help with both decontamination and thermoregulation.⁶¹

NERVE AGENTS

Physical Characteristics and Toxicity

Nerve agents are extremely potent organic phosphorus compound cholinesterase inhibitors, and are the most toxic of the known chemical weapons (Fig. 132–1).⁴⁶ For example, sarin is 1000-fold more potent in vitro than the pesticide parathion.⁷¹ Aerosol doses of nerve agents causing 50% human mortality (LD₅₀) range from 400 mg/minute/m³ for tabun down to 10 mg/minute/m³ for VX, compared with 2500 to 5000 mg/minute/m³ for hydrogen cyanide. Dermal exposure LD₅₀s for nerve agents range from 1700 mg for sarin down to only 6 to 10 mg for VX.^{46,71} Pure nerve agents are clear and colorless. Tabun has a faint fruity odor, and soman has been variably described as smelling sweet, musty, fruity, spicy, nutty, or like camphor. Most subjects exposed to sarin and VX have been unable to describe the odor.^{41,71} The G agents tabun (GA), sarin (GB), and soman (GD) are volatile and present a significant vapor hazard. Sarin is the most volatile, only slightly less so than water. VX is an oily liquid with low volatility and higher environmental persistence.^{41,46,71} Other G and V agents have been developed, including cyclosarin (GF) and Russian VX (VR).

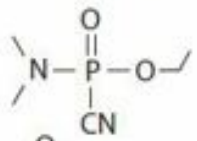

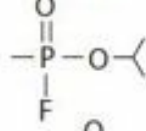

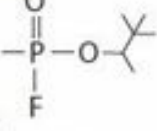

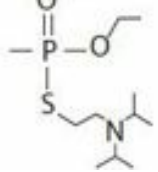

Military designation	Common name	Chemical name	Chemical structure
GA	Tabun	ethyl- <i>N,N</i> -dimethylphosphoramidocyanidate	
GB	Sarin	isopropyl-methylphosphonofluoridate	
GD	Soman	1, 2, 2-trimethylpropyl-methyl phosphonofluoridate	
VX	–	<i>O</i> -ethyl- <i>S</i> -(2-diisopropylaminoethyl)-methylphosphonothiolate	

FIGURE 132–1. Nerve agents.

Pathophysiology

The pathophysiology of nerve agents is essentially identical to that from organic phosphorus compound insecticides (Chap. 113), differing only in terms of potency and physical characteristics of the xenobiotics. The resultant toxic syndrome includes muscarinic (salivation, lacrimation, urination, defecation, GI cramping, emesis) and nicotinic (muscle fasciculation, weakness, paralysis) signs, and central effects (loss of consciousness, seizures, respiratory depression).^{29,69,73}

Clinical Effects

Nerve agent vapor exposures produce rapid effects, within seconds to minutes, whereas the effects from liquid exposure may be delayed as the agent is absorbed through the skin.⁷¹ Vapor or aerosol exposures have historically been more common, whether through experiments or from unintentional releases in the laboratory⁶⁹ or in terrorist attacks.^{48,57} Aerosol or vapor exposure initially affects the eyes, nose, and respiratory tract. Miosis is common, resulting from direct contact of nerve agent with the eye, and may persist for several weeks.^{69,73} Other ocular effects include conjunctival injection and blurring and dimming of the vision. Dim vision is often ascribed to pupillary constriction, but central neural mechanisms also play a role.⁷¹ Ciliary spasm produces ocular pain, headache, nausea, and vomiting, often exacerbated by near-vision accommodation.²⁹ Rhinorrhea, airway secretions, bronchoconstriction, and dyspnea occur with increasing exposures. With a large vapor exposure, one or two breaths may produce loss of consciousness within seconds, followed by seizures, paralysis, and apnea within minutes.⁴⁴

In the 1995 Tokyo subway sarin incident, ocular effects were most common after sarin vapor exposure, as patients

manifested miosis (89%–99% of symptomatic victims), eye pain, dim vision, and decreased visual acuity.^{29,57} Other common complaints were cough, throat tightness, nausea, headache, dizziness, chest discomfort, and abdominal cramping.^{43,78} Among 111 patients admitted to one hospital, the most common presenting signs and symptoms were miosis (99%), headache (74.8%), dyspnea (63.1%), nausea (60.4%), eye pain (45%), blurred vision (39.6%), dim vision (37.8%), and weakness (36.9%).^{53,57} Excessive secretions were less common, as rhinorrhea occurred in approximately one-quarter of patients admitted to one hospital,⁵⁷ and in none of 58 patients at another.⁷⁸ Secondary exposures occurred among emergency medical technicians (EMTs) and hospital personnel in both the Tokyo^{43,52,53} and Matsumoto^{48,49} terrorist sarin releases, apparently from evaporation of nerve agent that had condensed on the primary victims' clothing.

Liquid nerve agents can permeate ordinary clothing, allowing for percutaneous absorption and rendering the clothing of those patients' potential hazards to health care personnel prior to proper decontamination. Mild dermal exposure produces localized sweating and muscle fasciculations after an asymptomatic period lasting up to 18 hours. Moderate skin exposure produces systemic effects with nausea, vomiting, diarrhea, and generalized weakness. Substantial dermal contamination will produce earlier and more severe symptoms, often with abrupt onset. Severe toxicity from any route of exposure causes loss of consciousness, seizures, generalized fasciculations, flaccid paralysis, apnea, and/or incontinence.^{46,71,73} Cardiovascular effects are less predictable, as either bradycardia (muscarinic) or tachycardia (nicotinic) may occur.⁴⁴ In the Tokyo sarin event, tachycardia and hypertension were more common than bradycardia.^{51,78} Subtle CNS effects may continue for weeks, but typically resolve if no anoxic brain injury occurred.

Long-term effects from nerve agent exposure have mostly been limited to psychologic sequelae.⁶⁷ Neither delayed peripheral neuropathy nor the intermediate syndrome has been reliably described in humans exposed to nerve agents.^{73,74} Follow-up studies from the Japanese sarin incidents show that neuropathy and ataxia, when initially present, resolved within 3 days to 3 months.⁸⁵ The main persistent sequela is posttraumatic stress disorder, found in up to 8% of victims.^{28,85}

Treatment of Nerve Agent Exposure

Decontamination. In critically ill patients, antidotal treatment may be necessary before or during the decontamination process; but generally, decontamination should occur before other treatment is instituted.

Atropine. Atropine is the standard anticholinergic antidote for the muscarinic effects of nerve agents.¹⁷ Atropine does not reverse nicotinic effects but does have some central effects and may thus assist in halting seizure activity.^{29,41,71}

Atropine is administered parenterally, either by the intravenous (IV) or intramuscular (IM) route, and the dose is determined by titration to effect. The standard adult dose determined by the US military is 2 mg, an amount expected to produce substantial benefit in reversing nerve agent toxicity but one that should be tolerated by a healthy unexposed adult unintentionally receiving the drug.⁷¹ Current recommendations place the minimum initial dose of atropine in adults at 2 mg; dosing in children begins at 0.05 mg/kg for mild to moderate symptoms and 0.1 mg/kg for severe symptoms up to the adult dose.⁵ Severely poisoned adult patients receive an initial dose of 5 to 6 mg.^{29,71} Repeat doses are given every 2 to 5 minutes until resolution of muscarinic signs of toxicity. Therapeutic endpoints are drying of respiratory secretions and resolution of bronchoconstriction, bradycardia, and/or seizures (if initially present). Neither reversal of miosis nor development of tachycardia is a reliable marker to guide atropine therapy.²⁹ The total amount of atropine necessary to treat nerve agent poisoning is often much less than required for organic phosphorus insecticide toxicity of a similar degree. Typically, less than 20 mg is required in the first 24 hours, even in severe cases.^{29,71,73} Fewer than 20% of moderately ill patients admitted to one hospital for sarin poisoning in Tokyo required more than 2 mg atropine.⁵⁷

American troops in the 1990–1991 Gulf War were issued three MARK I kits for immediate field treatment of nerve agent poisoning. These kits are now also known as NAAKs, for nerve agent antidote kits. Each kit contains two autoinjectors: an AtroPen containing 2 mg of atropine in 0.7 mL diluent, and a ComboPen containing 600 mg of pralidoxime chloride (pyridine-2-aldoxime, 2-PAM) in 2 mL diluent.⁷¹ These autoinjectors permit rapid IM injections of antidote through protective clothing and are given in the lateral thigh.¹⁷ Treatment algorithms guided the number of MARK I kits to administer. In general, conscious casualties not in severe distress self-administer one kit (2 mg atropine), moderate to severe cases receive three kits (6 mg atropine) initially, and all receive additional doses as necessary, every 5 to 10 minutes.^{17,46,71} A combination atropine (2.1 mg) plus pralidoxime chloride (600 mg) autoinjector is available that gives both drugs with a single injection (Antidotes in Depth: A32).

In a nerve agent mass casualty incident, a hospital's intravenous atropine supplies may be rapidly depleted. Alternative sources include atropine from ambulances, ophthalmic and veterinary preparations, or substituting an antimuscarinic such as glycopyrrolate.²⁹ Atropine might also be stored as a bulk powder formulation and rapidly reconstituted for injection when needed.²⁰

Oximes. Oximes are nucleophilic compounds that reactivate organic phosphorus compound-inhibited cholinesterase enzymes by removing the dialkylphosphoryl moiety. The only oxime approved in the United States by the Food and Drug Administration is 2-PAM, a monopyridinium compound. Other pralidoxime salts are used elsewhere, such as the

methanesulfonate salt of pralidoxime (P2S) in the United Kingdom and 2-PAM methiodide in Japan. Other oximes include the bispyridinium compounds trimedoxime (TMB4) and obidoxime (toxogonin) used in other European countries^{41,57,71} Oximes should be given in conjunction with atropine, as they are not particularly effective in reversing muscarinic effects when given alone. Oximes are the only available nerve agent antidotes that can reverse the neuromuscular nicotinic effects of fasciculations, weakness, and flaccid paralysis (Antidotes in Depth: A33)

Oximes are effective only if administered before irreversible dealkylation, or “aging,” of the organic phosphorus compound-cholinesterase complex occurs. Soman has an aging half-life of 2 to 6 minutes in humans.¹⁶ It is unlikely that soman-poisoned victims will reach medical care early enough for oxime therapy to be of great benefit. For comparison, tabun has an aging half-life of about 14 hours, sarin 3 to 5 hours, and VX 48 hours.¹⁶ Pralidoxime is effective against sarin and VX in animal studies but not against tabun because of ineffective nucleophilic attack against that particular agent, and not because of aging issues. Obidoxime also is effective against sarin but not against tabun.⁴¹

The bispyridinium Hagedorn (H-series) oximes, particularly HI-6 and HLö-7, are also studied in the context of nerve agent toxicity.⁴¹ HI-6 appears beneficial against soman poisoning (possibly through direct pharmacologic action and/or reactivation of aged soman-inhibited ChE) but is not very effective against tabun. HLö-7 has reactivating activity for both soman-and tabun-inhibited ChE and may thus represent a universal oxime antidote for nerve agents. Administration of HI-6 and HLö-7 by autoinjector is difficult because they are not stable in aqueous solution.

For more details about pralidoxime administration, dosing, and adverse events, see Antidotes in Depth: A33. The ComboPen autoinjector in MARK I kits contains 600 mg pralidoxime, which produces a therapeutic maximal serum concentration of 6.5 µg/mL in average human volunteers.⁷¹ However, when possible, pralidoxime is optimally administered IV. Repeat pralidoxime dosing or continuous infusions are less likely to be needed for nerve agents than for organic phosphorus compound insecticides because severe effects are shorter-lived in properly decontaminated patients.²⁹

Anticonvulsants. Severe human nerve agent toxicity rapidly induces convulsions, which persist for a few minutes until the onset of flaccid paralysis. Diazepam is more beneficial than other anticonvulsants and simple γ-aminobutyric acid channel agonists due to its effects on choline transport across the blood–brain barrier and acetylcholine turnover.⁴¹ US military doctrine is to administer 10 mg diazepam IM by autoinjector at the onset of severe toxicity whether seizures are present or not. Thus, whenever three MARK I kits are used, a victim is also given diazepam. Additional autoinjectors are given by medical personnel as necessary for seizures.⁴⁶ The reason for the IM route of diazepam suggested above is related to timely administration under field conditions. If intravenous access is feasible, then IV diazepam in 5-mg doses IV every 15 minutes (≤ 15 mg) is recommended⁴¹ (Antidotes in Depth: A23)

Although diazepam is the most well studied benzodiazepine in the treatment of nerve agent toxicity, other medications in the same class such as lorazepam and midazolam should have similar beneficial effects. Armed service personnel of the United Kingdom have been supplied with ComboPens containing atropine sulfate (2 mg), pralidoxime mesylate (P2S; 30 mg), and avizafone (10 mg), a water-soluble prodrug of diazepam.⁸⁴

Pyridostigmine Pretreatment. The first large-scale use of pyridostigmine as a pretreatment for nerve agent toxicity occurred during Operation Desert Storm in 1991³³ Pyridostigmine is a carbamate acetylcholinesterase inhibitor that is freely and spontaneously reversible, whereas nerve agent inhibition is permanent once “aging” occurs. Toxicity from rapidly aging nerve agents such as soman (GD) can probably not be reversed by standard oxime therapy in realistic clinical situations. Almost paradoxically, then, a carbamate can occupy cholinesterase, blocking access of nerve agent to the active site, and thereby protect the enzyme from permanent inhibition. Following nerve agent exposure, pyridostigmine is rapidly hydrolyzed from acetylcholinesterase and can also be easily displaced by oximes, regenerating functional enzyme. Between 20% and 40% cholinesterase inhibition is desired to protect against nerve agents¹⁷ Doses of 60 mg of pyridostigmine bromide reduces cholinesterase activity by 28.4% in healthy individuals. Asthmatics taking 30 mg doses had a mean 24.3% reduction in cholinesterase activity without significant reductions in respiratory function or in response to inhaled atropine.⁵⁸ In animal studies, pyridostigmine confers a benefit against soman and tabun, but not against sarin or VX¹⁷ Also, it must be recognized that pyridostigmine is not an antidote, but is instead a pretreatment adjunct that greatly enhances the efficacy of atropine and oxime therapy⁷³

US troops in the 1990–1991 Gulf War took 30 mg pyridostigmine bromide orally every 8 hours when under threat of nerve agent attack. Cholinergic side effects, mostly gastrointestinal, were common but rarely required treatment.³³ Israeli soldiers taking the same dose also reported a range of mostly cholinergic symptoms but also a high incidence (71.4%) of dry mouth, which may be more related to environmental and psychological stressors.⁶⁶ Nine Israeli patients were hospitalized during the Gulf War for acute intentional pyridostigmine overdoses.² All patients recovered fully, including one patient who self-treated with atropine autoinjectors and presented with anticholinergic toxicity and another who suffered cardiac arrest, apparently from coingesting 4000 mg propranolol.

VESICANTS

Vesicants are agents that cause blistering of skin and mucous membranes (Fig. 132–2).

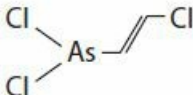

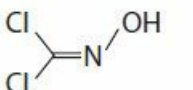

Military designation	Common name	Chemical name	Chemical structure
H, HD	Sulfur Mustard	bis-(2-chloroethyl) sulfide	
L	Lewisite	2-chlorovinyl dichloroarsine	
CX	Phosgene Oxime	dichloroformoxime	

FIGURE 132–2. Vesicants.

Sulfur Mustard

Sulfur mustard is bis(2-chloroethyl) sulfide, a vesicant alkylating compound similar to nitrogen mustards used in chemotherapy. Nineteenth-century scientists described the compound as smelling like mustard, tasting like garlic, and causing blistering of the skin on contact. The Allies of World War I called it Hun Stoffe (also called “German Stuff”), abbreviated as HS and later as just H. Distilled, nearly pure mustard is designated HD. The French called it Yperite, after the site where it was first used, and the Germans called it LOST after the two chemists who suggested its use as a chemical weapon, Lommel and Steinkopf. It was also called “yellow cross” after the markings on German artillery shells filled with mustard.^{10,14,75} Sulfur mustard caused over one million casualties in World War I,²¹ and was later used by the Italians and Japanese in the 1930s, by Egypt in the 1960s, and by Iraq in the 1980s.⁴⁶ About 100,000 Iranians from both military and civilian backgrounds were exposed to chemical warfare agents during the latter years of the Iran–Iraq war (1984–1988), many of whom are still suffering long-term effects.²² Nonbattlefield exposures have also occurred among Baltic Sea fishermen while recovering corroding shells dumped after WWII, and to persons unearthing or handling old chemical warfare ordinance.^{21,50,62,75}

Physical Characteristics

Sulfur mustard is a yellow to brown oily liquid with an odor resembling mustard, garlic, or horseradish. Mustard has relatively low volatility and high environmental persistence. Nonetheless, most historical mustard injuries occurred from vapor exposure, a danger that increases in warmer climates. Mustard vapor is 5.4 times denser than air. Mustard freezes at 57°F (13.9°C), so it is sometimes mixed with other substances, including chemical weapon agents like chloropicrin or Lewisite, to lower the freezing point and permit dispersion as a liquid.^{14,46,75}

Pathophysiology

Sulfur mustard toxicity occurs through several mechanisms. First, mustard is an alkylating agent. Mustard spontaneously undergoes intramolecular cyclization to form a highly reactive sulfonium ion that alkylates sulfhydryl (–SH) and amino (–NH₂) groups.^{10,14,46,75} The most important acute manifestation is indirect inhibition of glycolysis. Sulfur mustard rapidly alkylates and crosslinks purine bases in nucleic acids (Fig. 132–3). DNA repair mechanisms are activated, including the activation of the enzyme poly(ADP-ribose) polymerase,⁴² depleting NAD⁺, which, in turn, inhibits glycolysis, and ultimately leads to cellular necrosis from adenosine triphosphate depletion.¹⁰ Other mechanisms are probably involved, since the inhibition of glycolysis only partially correlates with the depletion of NAD⁺; sulfur mustard may also inhibit glycolysis directly through undetermined mechanisms.⁴² Mustard also depletes glutathione, leading to loss of protection against oxidant stress, dysregulation of calcium homeostasis, and further inactivation of sulfhydryl-containing enzymes.⁷⁵ Sulfur mustard is also a weak cholinergic agonist.^{46,75}

FIGURE 132–3. Mechanism of sulfur mustard toxicity: alkylation and DNA crosslinking.

Clinical Effects

The organs most commonly affected by mustard are the eyes, skin, and respiratory tract. During WWI, 80% to 90% of American mustard casualties had cutaneous lesions, 86% had ocular involvement, and 75% had airway injury. Iranian soldiers had more airway (95%) and ocular injuries (92%), and 83% had cutaneous lesions, probably because of the more extensive vaporization occurring in the warmer environment.^{10,75} Incapacitation may be severe in terms of number of lost man-days, time for lesions to heal, and increased risk of infection. In contrast, mortality is rather low. In WWI, only 2% to 3% of British mustard casualties and fewer than 2% of American casualties died. Fatality rates of 3% to 4% were reported from the Iran–Iraq War.¹⁰ Most deaths occur several days after exposure, either from respiratory failure, secondary bacterial pneumonia, or bone marrow suppression.

Dermal exposure produces dose-related injury. After a latent period of 4 to 12 hours, victims develop erythema that may progress to vesicles and/or bullae formation and skin necrosis. Warm, moist, and thin skin is at increased risk of mustard injury, in particular the perineum, scrotum, axillae, antecubital fossae, and neck. The vesicle fluid does not contain mustard because all chemical reactions are complete within a few minutes. If decontamination is not performed immediately after exposure, injury cannot be prevented. However, later decontamination may limit the severity of lesions and further spread of the agent. Skin exposure to vapor typically results in first- or second-degree burns, although liquid exposure may result in full-thickness burns.⁷⁵ Mustard easily penetrates normal clothing and uniforms, and many soldiers received gluteal, perineal, and scrotal burns from sitting on contaminated objects.

Latency of several hours also occurs following ocular and respiratory tract exposures. Ocular effects include pain, miosis, photophobia, lacrimation, blurred vision, blepharospasm, and corneal damage. Permanent blindness is rare, with recovery generally occurring within a few weeks. Inhalation of mustard results in a chemical tracheobronchitis. Hoarseness, cough, sore throat, and chest pressure are common initial complaints. Bronchospasm and obstruction from sloughed membranes occur in more serious cases, but lung parenchymal damage occurs only in the most severe inhalational exposures. Productive cough associated with fever and leukocytosis is common 12 to 24 hours after exposure, and

represents a sterile bronchitis or pneumonitis. Nausea and vomiting are common within the first few hours. High-dose exposures may also cause bone marrow suppression.^{10,46,75}

Various long-term sequelae are associated with sulfur mustard. Factory workers chronically exposed to mustard have increased risk of respiratory tract carcinomas, although the carcinogenic risk from battlefield exposures is more controversial.^{21,22,74} Respiratory sequelae include chronic bronchitis, emphysema, tracheobronchomalacia, and bronchiolitis obliterans.²² Mustard victims may also develop a delayed and often recurrent keratitis.^{21,68} Chronic dermatologic complications include scarring, pigmentation changes, and chronic, neuropathic pain, and pruritus.^{21,68} Among approximately 34,000 Iranians with confirmed exposure to sulfur mustard during the war with Iraq, chronic pulmonary sequelae were noted in 42.5%, ocular lesions in 39.3%, and dermatologic lesions in 24.5%.³⁵

Treatment

Decontamination is essential in treating the sulfur mustard exposures, even among asymptomatic victims. Further treatment is largely supportive and symptomatic.^{10,46,75} Victims may become blinded because of a combination of blepharospasm and corneal edema, which is temporary and completely resolves in most cases.

Several xenobiotics have been investigated as treatments for sulfur mustard injury. Antiinflammatory and sulphydryl-scavenging agents have shown benefit in animals as prophylactic therapy or if given immediately after exposure.⁷⁵ N-acetyl cysteine appears to be a promising therapeutic agent in cell culture and animal studies, although most of the evidence for its use relates to inhalational aerosol exposures to mustard.⁸ Neutropenia from bone marrow suppression can be treated with granulocyte colony-stimulating factor.⁴⁵

Lewisite. Lewisite (2-chlorovinyl-dichloroarsine) was developed as a less persistent alternative to avoid some shortcomings in the use of sulfur mustard in World War I. Lewisite was never used in combat because the first shipment was en route to Europe when the war ended, and it was intentionally destroyed at sea. British anti-Lewisite (BAL, dimercaprol) was developed as a specific antidotal agent and remains in use for chelation of arsenic and other metals.^{41,75}

Pure Lewisite is an oily, colorless liquid. Impure preparations are colored from amber to blue-black to black and have the odor of geraniums. Lewisite is more volatile than mustard and is easily hydrolyzed by water and by alkaline aqueous solutions such as sodium hypochlorite. These properties increase safety for offensive battlefield use, but make maintaining a potent vapor concentration difficult.

Lewisite toxicity is similar to that of sulfur mustard, resulting in dermal and mucous membrane damage, with conjunctivitis, airway injury, and vesiculation. An important clinical distinction is that Lewisite is immediately painful, whereas initial contact with mustard is not. Other differences are faster onset of inflammatory response and healing of lesions from Lewisite, less secondary infection of Lewisite lesions, and less subsequent pigmentation changes.⁷⁵ The mechanisms of Lewisite toxicity are not completely known, but appear to involve glutathione depletion and arsenical interaction with enzyme sulphydryl groups. Nevertheless, Lewisite toxicity is qualitatively and quantitatively different from the arsenic it contains. Treatment consists of decontamination with copious water and/or dilute hypochlorite solution, supportive care, and BAL. BAL is given parenterally for systemic toxicity and is also used topically for dermal or ophthalmic injuries. Alternative metal chelators that may be used as Lewisite antidotes include dimercaptopropane sulfonate and succimer (2,3-dimercaptosuccinic acid).⁴¹

Phosgene Oxime. Although classified as a vesicant, phosgene oxime (dichloroformoxime, or CX) does not cause vesiculation of the skin. CX is more properly an urticant or “nettle” agent, in that it produces erythema, wheals, and urticaria likened to stinging nettles. Phosgene oxime produces immediate irritation of the skin and mucous membranes. CX has never been used in battle, and little is known about its mechanism or effects on humans.^{46,75}

CYANIDES (CHEMICAL ASPHYXIANTS)

Several cyanides have been used as chemical weapons. During World War I, the French used hydrogen cyanide (HCN) and cyanogen chloride (CNCl), designated as agents AC and CK, respectively, without great success; the Austrians introduced cyanogen bromide (CNBr). Cyanide weapons are relatively ineffective because of rapid dispersion and their “all or nothing” biologic activity. An exposed individual either rapidly succumbs to cyanide toxicity, or will rapidly recover with minimal sequelae. Mass casualty events from cyanide CW are reported during the Iran–Iraq War and from Iraq’s suppression of the Kurds.^{6,46}

The clinical effects and treatment of cyanide toxicity are covered elsewhere ([Chap. 126](#)) and do not differ significantly if used as a weapon. Hydrocyanic acid gas persists for only a few minutes in the atmosphere, because it is lighter than air and rapidly disperses. Cyanogen chloride additionally causes ophthalmic and respiratory tract irritation and can produce delayed acute lung injury in victims who are not rapidly killed.^{6,46}

PULMONARY IRRITANTS

Both chlorine and phosgene were used as war gases in World War I. Chlorine, phosgene, various organohalides, and nitrogen oxides belong to a group of toxic chemicals designated “pulmonary irritants” because they can all induce delayed ARDS from increased alveolar-capillary membrane permeability.^{41,46,82} Although pulmonary agents have not been used militarily since 1918, the risk of chlorine and phosgene exposure remains because of their extensive use in industry, or possibly as a terrorist weapon (Chap. 124), for clinical details, as the remainder of this section highlights mass-casualty issues regarding these irritants.

When released on the battlefield, chlorine forms a yellow-green cloud with a distinct pungent odor detectable at concentrations that are not immediately dangerous. Phosgene is either colorless or seen as a white cloud as a result of atmospheric hydrolysis. Phosgene, which is reported to smell like grass, sweet newly mown hay, corn, or like moldy hay, accounted for about 85% of all World War I deaths attributed to chemical weapons.^{10,41} Phosgene produces injury by hydrolysis in the lungs to hydrochloric acid and by forming diamides that cross-link cell components (Fig. 132–4). Similar cross-linking reactions may occur with hydroxyl and thiol groups. Battlefield exposure triggers cough, chest discomfort, dyspnea, lacrimation, and the peculiar complaint that smoking tobacco produces an objectionable taste. World War I phosgene fatalities were noted to develop a mushroom-shaped efflux of pink foam at their mouths from pulmonary edema fluid. Prolonged observation after phosgene exposure is the rule, as some casualties initially appeared well and were discharged, only to return in severe respiratory distress a few hours later.^{41,46,82} Exercise appeared to precipitate ARDS in phosgene casualties.⁶³ For American soldiers in World War I, the average time spent recovering away from the front was 60 days for chlorine and 45.5 days for phosgene.¹⁹

FIGURE 132–4. Proposed mechanism of phosgene toxicity. (A) Phosgene reacts with amine group to form an amide, releasing hydrochloric acid. (B) A second reaction crosslinks two amine equivalents, forming a diamide.

RIOT CONTROL AGENTS

Riot control agents (Fig. 132–5) are intentionally non-lethal chemicals that temporarily disable exposed individuals through intense irritation of exposed mucous membranes and skin. These agents are also known as lacrimators, irritants, harassing agents, human repellents, and tear gas. They are solids at normal temperatures and pressures, but are typically dispersed as aerosols or as small solid particles in liquid sprays. Common characteristics include rapid onset of effects within seconds to minutes, relatively brief duration once exposure has ceased and the victim is decontaminated, and a high safety ratio (lethal dose vs effective dose).^{41,46,72}

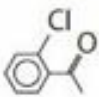

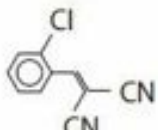

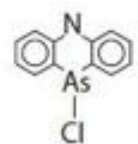

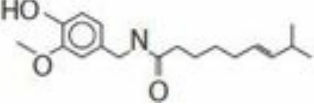

Military designation	Common name	Chemical name	Chemical structure
CN	Chemical mace	1-chloroacetophenone	
CS	Tear gas	o-chlorobenzylidene malononitrile	
DM	Adamsite	diphenylaminechlorarsine	
OC	Capsaicin pepper spray	<i>trans</i> -8-methyl- <i>N</i> -vanillyl-6-noneamide	

FIGURE 132–5. Riot control agents.

Chloroacetophenone (CN) is the active ingredient in the Chemical Mace brand nonlethal weapon.⁷⁷ *o*-Chlorobenzylidene malononitrile (CS) has largely replaced CN because of its higher potency, lower toxicity, and improved chemical stability.^{38,72} When used for crowd control, both CN and CS are disseminated as aerosols or as smoke from incendiary devices. Exposed persons develop burning irritation of the eyes, progressing to conjunctival injection, lacrimation, photophobia, and blepharospasm. Mucous membranes of the upper aerodigestive tracts can also be involved. Inhalation causes chest tightness, cough, sneezing, and increased secretions. Dermal exposure may cause a burning sensation, erythema, or vesiculation, depending on the dose. Victims generally remove themselves from the offensive environment (which is the primary purpose of their use as “riot control” agents) and recover within 15 to 30 minutes. Deaths are rare, and typically occur from respiratory tract complications in closed-space exposures where exiting the area is impossible.^{41,46,72}

The biologic mechanism whereby riot-control agents exert their effects is less well described than for other chemical weapons. CS and CN are SN_2 alkylating agents (versus sulfur mustard, an SN_1 alkylator) and react with sulfhydryl-containing compounds and enzymes. For instance, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme for pyruvate decarboxylase. Tissue injury may be related to inactivation of certain enzyme systems. Pain in the absence of tissue injury may be bradykinin mediated.⁴⁶

Personal protective devices dispensing lacrimator substances also cause chemical injuries in the absence of war or civil unrest. Law enforcement agencies and private citizens may have access to products containing CS, CN, and/or (oleoresin capsicum {OC}, also known as pepper spray). OC is the essential oil derived from pepper plants (*Capsicum anuum*), which contains capsaicin (*trans*-8-methyl-*N*-vanillyl-6-noneamide), a naturally occurring lacrimator. Capsaicin activates heat-dependent nociceptors, explaining why exposures are experienced as “hot.”¹² Severe respiratory tract injuries and fatalities are occasionally reported from exposures to these devices, typically only with prolonged or highly concentrated exposures. A synthetic capsaicinoid, pelargonic acid vanillylamide (PAVA) in spray form has recently been approved as an incapacitant for police use in the United Kingdom.⁴ PAVA is believed to be safer than CS, but no published medical experience with this agent is yet available. A capsaicin-containing riot control device called Pepperball Tactical Powder has caused severe localized skin injuries.²⁵ This device is a pellet of powdered capsaicin (and carrier substances) pressurized within a thin plastic shell fired as a munition.

Chloropicrin (trichloronitromethane, or nitrochloroform) is another lacrimator that occasionally causes human toxicity through its use as a fumigant and soil insecticide.⁷⁹ 10-chloro-5,10-dihydrodiphenarsazine (or diphenylaminearsine {DM}) is a vomiting agent. Clinical effects are delayed for several minutes after exposure, by which time the victim may have absorbed a significant amount. In addition to upper respiratory and ocular irritation, diphenylaminearsine causes more prolonged systemic effects with headache, malaise, nausea, and vomiting.^{46,72}

The primary treatment for all riot control agents is removal from exposure. Contaminated clothing should be removed and placed in airtight bags to prevent secondary exposures.³⁸ Skin irrigation with copious cold water is used for significant dermal exposures.^{7,38,39} Symptomatic treatments, such as with topical ophthalmic anesthetics, nebulized bronchodilators, or oral antihistamines and corticosteroids, are indicated as appropriate in more severely affected victims.⁷ Capsaicin-induced dermatitis has been treated variably with immersion in water or oil, vinegar, bleach, lidocaine gel, and topical antacid suspensions.^{27,31,77} Cold water produces earlier symptomatic relief, but oil immersion has longer-lasting benefit.³¹

INCAPACITATING AGENTS

3-Quinuclidinyl benzilate (BZ or QNB; Fig. 132–6) is an antimuscarinic compound that was developed as an incapacitating CW agent. BZ is 25-fold more potent centrally than atropine, with an ID_{50} (dose that incapacitates 50% of those exposed) of about 0.5 mg. Clinical effects are characteristic for anticholinergics, with drowsiness, poor coordination, and slowing of thought processes progressing to delirium. BZ takes at least 1 hour to produce initial manifestations, peaks at 8 hours, continues to incapacitate for 24 hours, and takes 2 to 3 days to fully resolve.³⁴ During the recent Balkan Wars of the 1990s, allegations were made that Bosnian Serbs used BZ against civilians, who reported hallucinations associated with attacks by artillery shells emitting smoke.²⁴

FIGURE 132–6. Incapacitating agent BZ (3-quinuclidinyl benzilate {QNB}).

Ultrapotent opioids may also be used as incapacitating CW agents. In 2002, Russian security forces used a fentanyl derivative (possibly carfentanil or remifentanyl) to end a 3-day standoff with terrorists in a Moscow theater in which Chechen rebels held more than 800 hostages.⁸³ A “gas” was introduced into the theater ventilation system, which quickly subdued the occupants. More than 650 of the hostages were hospitalized, and 128 died. Initial news reports suggested the use of BZ, although the clinical findings were more consistent with a CNS depressant. Within a few days, Russian officials stated that the agent used was a fentanyl derivative and was not expected to cause fatalities. The relatively high case fatality rate could be because of multiple factors, including variability in dose, displacement of oxygen by rapid introduction of gas into the building, failure to adequately notify health care teams and supply them with antidotes, and poor physical condition of the hostages.

Lysergic acid diethylamide (LSD) has also been investigated as an incapacitating agent.³⁴ Although effective at very low doses, battlefield use of LSD is impractical since intoxication will not reliably prevent a soldier from participation in combat.

Table 132–5 describes the various toxic syndromes that may be seen from use of CW agents.

TABLE 132–5. Chemical Weapons Toxic Syndromes

Chemical/Weapon	Organ System							
	Onset	Eyes	Upper Airways and Mucous Membranes	Lungs	Skin	CNS	GI Tract	Other
Nerve Agents								
Tabun (GA), Sarin (GB), Soman (GD), VX								
Aerosol/vapor (Mild/moderate exposure)	Rapid (seconds–minutes)	Miosis, eye pain, dim or blurred vision	Rhinorrhea, ↑ secretions	Dyspnea, cough, wheezing, bronchospasms	—	Headache	Nausea, vomiting, abdominal cramps	—
Dermal exposure (Mild/moderate exposure)	Delayed (minutes–hours)	—	—	—	Localized sweating	—	Nausea, vomiting, diarrhea, cramping	Subjective weakness, local muscle fasciculations
Severe exposure (any route)	As above (by route)	Miosis	↑ Secretions	Apnea	—	Sudden collapse, seizures	Incontinence	Generalized fasciculations, weakness, flaccid paralysis
Vesicants								
Sulfur mustard (H, HD)	Delayed (hours)	Conjunctivitis, eye pain, blurred vision, blindness (temporary)	Irritation, hoarseness, early cough, sinus tenderness, tracheobronchitis	(More severe exposures) Productive cough, pseudomembrane formation, airway obstruction	Erythema, vesicles, bullae, necrosis	—	Nausea, vomiting	Bone marrow suppression (in severe exposures)
Lewisite (L)	Immediate irritation Delayed vesication	Pain, blepharospasm, conjunctivitis, lid edema	(Same as Sulfur Mustard)	(Same as Sulfur Mustard)	Erythema, vesicles	—	—	Shock (in severe exposures)
Phosgene oxide (CX)	Immediate irritation Delayed irritation	Pain, corneal damage	Irritation	ARDS	Pain, blanching, erythema, urticaria, necrosis	—	—	—
Pulmonary Agents								
Phosgene (CG)	Immediate irritation	Irritation	Irritation, strike (Chlorine)	Dyspnea, cough, ARDS	—	—	—	Chlorine effects more rapid than phosgene
Chlorine (CL)	Delayed ARDS							
Cyanides								
Hydrogen cyanide (AC)	Rapid (seconds–minutes)	—	—	Hyperpnea then apnea	—	Anxiety, agitation, sudden collapse, seizures	—	—
Cyanogen chloride (CK)	Rapid (seconds–minutes)	Irritation	Irritation	Hyperpnea then apnea	—	Anxiety, agitation, sudden collapse, seizures	—	—
Riot Control Agents								
Lacrimators (CN, CS) Capsaicin (OC)	Immediate	Pain, lacrimation, blepharospasm, conjunctivitis	Irritation	Cough, chest pain	Burning pain, erythema Vesiculation (severe exposures)	—	Nausea, itching (may occur with CN/CS)	—
Adamsite (DM)	Rapid (minutes)	Irritation	Irritation, sneezing	Cough, chest pain	—	Headache	Nausea, vomiting, abdominal cramps	—
Incapacitating Agent								
3-quinacridinyl benzoate (BZ)	Delayed (hours)	Mydriasis	Dry mouth	—	—	Anticholinergic delirium	—	—
Ultra-potent opioids	Rapid (seconds–minutes)	Miosis	—	Hypoventilation	—	CNS depression	—	—

SUMMARY

- CBW agents are appealing to terrorist groups because the impact in terms of death, disability, economic losses, and panic remains high.
- The psychological impact of CBW terrorism may well exceed that for conventional or nuclear weapons.
- Although the probability of incidents resulting in widespread public health disasters appears low, the consequences are high, and substantial preparations must be made in advance.
- Early decontamination is often critical for victims exposed to chemical warfare agents.
- Nerve agents are potent organic phosphorus compound acetylcholinesterase inhibitors. Toxicity produces cholinergic toxicity, which is treated with antimuscarinics, particularly atropine, and oximes.
- Vesicant chemical weapons induce blistering of the skin and damage to other tissues in contact, such as the eyes or respiratory tract. Sulfur mustard has no specific antidote, but the arsenic containing Lewisite can be treated with BAL, a chelator.
- Exposure to chlorine, phosgene, ammonia and some other gases can produce delayed ARDS. Although used on the battlefield in World War I, it is expected that intentional use of these pulmonary irritant gases is now more likely to occur from their use by terrorists as “agents of opportunity.”

133 BIOLOGICAL WEAPONS

Jeffrey R. Suchard

Expertise in dealing with biological weapons requires specific knowledge from the fields of infectious disease, epidemiology, toxicology, and public health. Biological and chemical warfare agents share many characteristics in common, including intent of use, some dispersion methods, and initial defense based on adequate personal protective equipment and decontamination (Tables 132–2 and 132–3). However, key differences between biological and chemical weapons involve a greater delay in onset of clinical symptoms after exposure to biological weapons; that is, the incubation period for most bioweapons (BW) is greater than the latent period for most chemical warfare agents. Decontamination is less crucial for victims exposed to BWs than to chemical warfare agents. Additionally, a few BWs can reproduce in the human host and cause secondary casualties, and disease following exposure to several of these agents can be prevented by the timely administration of prophylactic medications.

BWs may be bacteria, fungi, viruses, or toxins derived from microorganisms. Some fungi are listed as potential BWs; however, none are known to have been developed into weapons to date.⁶⁹ Because toxin weapons are not living organisms, some authorities classify them as chemical, rather than biological weapons. For the purpose of discussion in this chapter, toxin weapons derived from microorganisms will be considered BWs. Most of the bacterial BWs exert their effects by elaborating protein toxins.

Many diseases caused by biological weapons are either infrequently encountered in modern clinical medicine, such as anthrax and plague, or no longer occur naturally, such as smallpox. Therefore, health care personnel require specific training in recognizing and managing biological warfare victims. Potential BWs are categorized by their risk of causing mass-casualty outbreaks.¹⁴ The high-risk BWs are more easily disseminated or transmitted and may cause high mortality and potential public health disasters; these BWs include smallpox, anthrax, plague, botulism, tularemia, and several hemorrhagic fever viruses. The moderate-risk agents include Q fever, brucellosis, the equine encephalitis viruses, ricin, and staphylococcal enterotoxin B, all of which are briefly discussed in this chapter.

HISTORY

Biological warfare has ancient roots. Missile weapons poisoned with natural toxins were used as early as 18,000 years ago (Chap. 1). Other uses of biological warfare prior to the modern era relied mainly on poisoning water supplies with natural toxins, or spreading naturally occurring epidemic infections to the enemy by hurling infected corpses over battlements or through the intentional transfer of disease-contaminated goods (eg, smallpox blankets).

During World War I, Germany was the only combatant nation with an active BW program; however, by World War II many nations had BW research programs, including Japan, the Soviet Union, Germany, France, Britain, Canada, and the United States. The Japanese program included field trials with bubonic plague and conducted BW experiments on prisoners of war and civilians.³⁵ The American program was founded at Camp Detrick, Maryland, in 1942. Fort Detrick, as it is now known, remains the home of the United States Army Medical Research Institute of Infectious Diseases (USAMRIID). Anthrax and botulinum toxin were the foci of American BW development during World War II. The British program was established at Porton Down in 1940, but most of their field testing of anthrax occurred on Gruinard Island off the northern coast of Scotland, resulting in long-term soil contamination with anthrax spores.

In London, in 1978, the Bulgarian exile Georgi Markov was assassinated with a tiny metal pellet fired from a gun designed to appear like an umbrella. He was originally thought to have died from sepsis until the pellet was found at autopsy.²³ After the fall of the Soviet Union, government officials confirmed that the KGB used umbrella guns firing ricin pellets to assassinate Markov and others.

In 1979, an outbreak of human anthrax caused at least 66 fatalities in the Russian city of Sverdlovsk. Autopsies revealed that the deaths were from inhalational anthrax, and epidemiologic investigation demonstrated that almost all the cases occurred downwind from a military facility. These data are consistent only with a release of aerosolized anthrax, which has since been confirmed by Russian authorities.⁵¹

In the late 1970s and early 1980s, many reports came from Southeast Asia and Afghanistan that Soviet-supported troops were using a biological weapon known as Yellow Rain.⁶⁸ Some samples of Yellow Rain were found to contain trichothecene mycotoxins, although controversy remains as to whether this represents intentional biological warfare or was

a naturally occurring phenomenon.⁶⁰

During the 1990s, concern arose regarding the use and possible stockpiling of weapons of mass destruction (WMD) in Iraq.⁴⁵ Iraq had an active BW research program, investigating at least five bacteria, one fungus, five viruses, four toxins, and a variety of dispersion methods.^{61,71} Thousands of liters of anthrax spores, botulinum toxin, and aflatoxin were produced and weaponized into bombs and as payloads for SCUD missiles.

Biological terrorism and the threat of bioterrorism are now recognized as worldwide, growing public health concerns.³⁶ In 1984, a large outbreak of salmonellosis was traced to intentional contamination of restaurant salad bars by the Rajneeshee cult in Oregon.⁶⁶ The Aum Shinrikyo cult based in Japan investigated the use of cholera and Q fever, unsuccessfully released anthrax spores and botulinum toxin, and even sent members to Africa to obtain the Ebola virus.^{55,64} The mere threat of a BW release can terrorize a city. At the end of the 1990s, there was a huge increase in false anthrax threats, which paralyzed Los Angeles and cities in Indiana, Kentucky, and Tennessee, among many others.¹³

In 2001, closely following the September 11, 2001, attack on New York and Washington, DC, a bioterrorist attack occurred in the United States resulting in several cases of inhalational and cutaneous anthrax, with five fatalities. After years of investigation, suspicion regarding the culprit for this event was directed toward Bruce Ivins, a microbiologist who worked at USAMRIID, and would therefore have had potential access to weaponized anthrax spores. No direct evidence linked Dr. Ivins to the incident, and he had not yet been formally charged with any crime, when he died from a suicidal acetaminophen overdose in 2008.

GENERAL CONSIDERATIONS

Differences Between BW Incidents and Naturally Occurring Outbreaks

Because the clinical effects of BWs are often delayed for several days after exposure, it may be difficult to differentiate occult BW releases from naturally occurring disease outbreaks. Several epidemiologic criteria are proposed to aid in such determinations,⁵⁴ many of which should be identifiable in a BW incident (Table 133–1).

TABLE 133–1. Epidemiologic Clues Suggesting Biological Weapon Release

- Large epidemic with unusually high morbidity and/or mortality
- Epidemic curve (number of cases vs. time) showing an “explosion” of cases, reflecting a point source in time rather than insidious onset
- Tight geographic localization of cases, especially downwind of potential release site
- Predominance of respiratory tract symptoms because most bioweapons are transmitted by aerosol inhalation
- Simultaneous outbreaks of multiple unusual diseases
- Immunosuppressed and elderly persons more susceptible
- Nonendemic infection (“impossible epidemiology”)
- Nonseasonal time for endemic infection
- Organisms with unusual antimicrobial resistance patterns, reflecting BW genetic engineering
- Animal casualties from same disease outbreak
- Absence of normal zoonotic disease host
- Low attack rates among persons incidentally working in areas with filtered air supplies or closed ventilation systems, using HEPA masks, or remaining indoors during outdoor exposures
- Delivery vehicle or munitions discovered
- Law enforcement or military intelligence information
- Claim of bioweapon release by belligerent force

To avoid early detection, terrorists might choose to release a BW causing endemic infection, or a disease that mimics an endemic infection, during its season of peak incidence. In some areas of the United States, for example, a few cases of bubonic plague would not attract notice until, perhaps, dozens or hundreds of cases were identified. An outbreak of inhalational anthrax during the influenza season may similarly be hidden among patients with shared early symptoms until an unusually high mortality was evident.¹⁹ By the time the BW outbreak was recognized, the perpetrators could dispose of any physical evidence and flee the area. Alternatively, even a single case of smallpox (anywhere in the world), or Ebola virus disease or Congo-Crimean hemorrhagic fever (in nonendemic areas) should immediately raise suspicion of a BW attack.

Preparedness

Many BWs initially produce nonspecific symptoms, and diseases that rarely, if ever, occur in clinical practice. Inhalational

anthrax and pneumonic plague, for example, could easily be misdiagnosed as influenza or acute bronchitis. Providers in emergency departments (EDs) and primary care medicine must be educated to recognize the signs, symptoms, and clinical progression of diseases caused by BW.⁵⁹ Clear identification, isolation, and aggressive treatment early after exposure within the first 24 to 48 hours are the best and only means of reducing mortality and, in the case of smallpox or plague, preventing secondary or tertiary cases.²⁷ However, in spite of increasing awareness and educational opportunities, many physicians remain inadequately prepared.

Decontamination

Bioweapons are most effective when dispersed by aerosol. Shortly after a known or suspected release of bioaerosols, decontamination is a relatively minor concern because aerosols sized to reach the lower respiratory tract ($< 5\text{-}\mu\text{m}$ particles) produce little surface contamination. However, simple removal of clothing will eliminate a high proportion of deposited particles, and subsequent showering with soap and water will probably remove 99.99% of any remaining organisms on the skin.⁴⁴ Thus, decontamination after BW aerosol exposure, when needed, is achieved through disrobing and showering with soap and water. This can be done onsite or in the victims' homes and away from health care facilities, thereby reducing strain on disaster response manpower and material in multiple-victim exposures.^{27,36,44,59} When there is gross, visible evidence of skin exposure to a BW, the patient should be decontaminated by thorough irrigation, and, if available, sterilizing the skin with a sporicidal/bactericidal solution (eg, 0.5% sodium hypochlorite), and a final water rinse.^{44,59} After an occult BW release, victims are identified late after exposure; decontamination will obviously not be helpful and may only serve to delay care.

BIOLOGICAL WARFARE AGENTS

Bacteria

Anthrax. Anthrax is caused by *Bacillus anthracis*, a Gram-positive spore-forming bacillus found in soil worldwide (Figs. 133–1 and 133–2). *B. anthracis* causes disease primarily in herbivorous animals. Human anthrax cases generally occur in farmers, ranchers, and among workers handling contaminated animal carcasses, hides, wool, hair, and bones³²

FIGURE 133–1. Anthrax Gram stain.

FIGURE 133–2. Anthrax spores.

Clinical manifestations. A few clinically distinct forms of anthrax may occur, depending on the route of exposure. Cutaneous anthrax results from direct inoculation of spores into the skin via abrasions or other wounds and accounts for about 95% of endemic (naturally occurring) human cases. Patients develop a painless red macule that vesiculates, ulcerates, and forms a 1-to 5-cm brown-black eschar surrounded by edema.⁴⁸ The eschar color gave rise to the name anthrax, from the Greek word *anthrakos* meaning “coal.” Most skin lesions heal spontaneously, although 10% to 20% of untreated patients progress to septicemia and death. When treated with antibiotics cutaneous anthrax rarely results in fatalities. Anthrax is not transmissible among humans.

Gastrointestinal (GI) anthrax results from ingesting insufficiently cooked meat from infected animals. Patients develop nausea, vomiting, fever, abdominal pain, and mucosal ulcers, which can cause GI hemorrhage, perforation, and sepsis. Mortality from GI anthrax is at least 50%, even with antibiotic treatment.³²

Inhalational anthrax results from exposure to aerosolized *B. anthracis* spores. Although this form of anthrax is very rare, it is so closely associated with occupational exposures that it is called “wool-sorter’s disease.” Inhalational anthrax is also likely to be the form that occurs in a BW attack, because the anthrax spores would be most effectively disseminated by aerosol. After an incubation period of 1 to 6 days, the patient develops fever, malaise, fatigue, nonproductive cough, and mild chest discomfort, which may be easily mistaken for community acquired pneumonia.¹⁹ The initial symptoms may briefly improve for 2 to 3 days or the patient may abruptly progress to severe respiratory distress with dyspnea, diaphoresis, stridor, and cyanosis. Bacteremia, shock, metastatic infection such as meningitis, which occurs in about 50% of cases, and death may follow within 24 to 36 hours. Prior to the 2001 bioterrorist outbreak, mortality from inhalational anthrax was expected to be nearly 100%, even with antibiotics, once symptoms develop.^{30,32} With appropriate antibiotic therapy and supportive care, 5 of 11 patients with inhalational anthrax in 2001 died, and although this is still a high mortality rate, it is less than that previously predicted.⁴⁰

Pathophysiology. Inhalational anthrax causes a mediastinitis. Diagnostic imaging typically shows mediastinal widening from enlarged hilar lymph nodes and pleural effusions, although pulmonary parenchymal infiltrates may also be seen.⁴⁰ Inhaled spores are taken up into the lymphatic system where they germinate and the bacteria reproduce. *B. anthracis* produces three toxins: protective antigen, edema factor, and lethal factor. Protective antigen (PA) is so named because antibodies against it protect the individual from the effects of the other two toxins. PA forms a heptamer that inserts into plasma membranes, facilitating endocytosis of the other two toxins into target cells (Fig. 133–3). Edema factor is a calmodulin-dependent adenylate cyclase. Increased intracellular cyclic adenosine monophosphate (AMP) upsets water homeostasis, leading to massive edema and impaired neutrophil function. Lethal factor is a zinc metalloprotease that stimulates macrophages to release tumor necrosis factor α and interleukin-1 β , contributing to death in systemic anthrax infections.²⁵ The combination of PA plus edema factor is called edema toxin, while PA plus lethal factor is lethal toxin.³⁴

FIGURE 133–3. Model of action of anthrax toxins. EF and LF are unable to enter cells until they complex with a PA heptamer, forming edema toxin and lethal toxin, respectively. Once intracellular, release from PA allows EF and LF to exert their intracellular effects. Antibodies against PA confer resistance to the toxic effects of anthrax. EF = edema factor; LF = lethal factor; PA = protective antigen; PK = protein kinase.

Treatment. The primary antibiotics recommended to treat anthrax are ciprofloxacin and doxycycline. Although other fluoroquinolones would be expected to have similar activity against anthrax, only the manufacturer of ciprofloxacin applied for and received a US Food and Drug Administration (FDA)-approved indication for use in this infection. In a mass-casualty setting or for postexposure prophylaxis, adults should be treated with ciprofloxacin 500 mg orally (PO) every 12 hours. Alternate therapies are doxycycline 100 mg PO every 12 hours, or amoxicillin 500 mg PO every 8 hours, if the anthrax strain is proven susceptible⁴⁰ The recommended duration of therapy is 60 days, stemming from case experience in Sverdlovsk where some patients developed disease several weeks (6–7 weeks) after the spore release⁵¹ Children can also be treated with ciprofloxacin (15 mg/kg; maximum 500 mg/dose) or amoxicillin (80 mg/kg/d divided every 8 hours; maximum 500 mg/dose). The relative pediatric contraindication to fluoroquinolones is outweighed by the risk of potentially fatal disease. Cutaneous anthrax is treated with the same drugs and doses as for postexposure prophylaxis

Inhalational anthrax should be treated initially with intravenous antibiotics. Adults should receive ciprofloxacin 400 mg intravenously (IV) or doxycycline 100 mg IV every 12 hours, along with one or two additional antibiotics with in vitro activity against anthrax (eg, rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, clarithromycin). Children should be given ciprofloxacin 10 mg/kg IV (maximum 400 mg/dose), or doxycycline 2.2 mg/kg IV (maximum 100 mg/dose), and additional antibiotics, as indicated above.⁴⁰ However, in a true mass-casualty event, when resources are strained and inpatient care is not available for every victim, oral therapy, as described above, may be instituted. When clinically appropriate, PO antibiotic therapy can be substituted for IV forms, with total treatment duration of 60 days. Some patients in the 2001 outbreak were specifically treated with additional antibiotics that inhibit protein synthesis in attempts to reduce bacterial production of toxins.

Anthrax vaccine. An effective vaccine against anthrax is available^{33,50,72} In the United States, the Bioport Corporation (formerly Michigan Biologic Products Institute) is licensed by the FDA to produce anthrax vaccine adsorbed (AVA). The vaccine consists of a membrane-sterilized culture filtrate of *B. anthracis* V770-NP1-R, an avirulent, nonencapsulated strain that produces protective antigen, adsorbed to aluminum hydroxide, formulated with benzethonium chloride (preservative) and formaldehyde (stabilizer)⁷² In human and animal experiments, the vaccine is highly effective in preventing all forms of anthrax, and the vaccine is recommended for workers in high-risk occupations. As with any vaccine, local reactions to AVA occur in some recipients (up to 20% with mild, local reactions), and self-limited systemic reactions occur more rarely (< 1.5%). Women have more frequent injection-site reactions and other adverse events, although this sex difference is also noted with other common vaccines³⁴ Serious adverse events are very rare, with only 22 potentially related cases of serious adverse events from over 1 million doses administered to US armed forces³³ The dosage schedule for AVA is 0.5 mL subcutaneously at 0, 2, and 4 weeks and 6, 12, and 18 months, followed by yearly boosters. Preclinical studies have also been conducted on a human monoclonal antibody against protective antigen, which has been developed as an antitoxin for use in the treatment of inhalational anthrax

2001 bioterrorist anthrax outbreak. Starting on September 27, 2001, a 63 year-old Florida man developed malaise, fatigue, fever, chills, anorexia, and diaphoresis. He was admitted to a local hospital on October 2, after presenting with additional complaints of nausea, vomiting, and confusion. Chest radiography showed cardiomegaly, a left perihilar infiltrate, small left pleural effusion, and a prominent superior mediastinum. Lumbar puncture revealed hemorrhagic meningitis with many Gram-positive bacilli *Bacillus anthracis* was isolated from the cerebrospinal fluid after only a 7-hour incubation and from blood cultures within 24 hours. The patient had progressive clinical deterioration and died on hospital day four^{10,42}

On October 4, the US Centers for Disease Control and Prevention (CDC) released a public health message regarding

this case, which initially appeared to be an isolated, perhaps naturally occurring sporadic event.¹⁵ Nevertheless, the rarity of inhalational anthrax especially outside of a high-risk occupation, combined with increased suspicion in the wake of the September 11, 2001, attacks led to intense investigation of a potential bioterrorist event. Within days, epidemiologic investigation suggested workplace exposure to anthrax spores, and personnel working in the same building were started on prophylactic ciprofloxacin.¹⁶ On October 12, a case of cutaneous anthrax was reported in New York associated with a suspicious letter opened on September 25.¹⁷ Anthrax cases and environmental contamination were also soon detected in Washington, DC, and in a New Jersey postal facility. The public response to the reports of these serious and fatal cases included misuse and hoarding of antibiotics, purchasing gas masks (often with inappropriate filtering mechanisms for BW), reporting numerous miscellaneous powdery substances, and perpetrating or reporting copycat hoaxes.

By November 7, 2001, a total of 22 cases of anthrax were reported: 10 inhalational and 12 cutaneous.¹⁸ One additional death from inhalational anthrax occurred on November 21, 2001,⁴ and a case of cutaneous anthrax also occurred in a laboratory worker analyzing samples obtained during the investigation.²⁰ In two of the fatal cases, no contact with contaminated letters could be established.^{4,53} One infant hospitalized in New York with cutaneous anthrax was initially misdiagnosed as suffering from a brown recluse spider envenomation.³¹ The total number of medical victims of anthrax by Spring 2002 was 23:11 cases of inhalational anthrax (with five fatalities), and 12 cases of cutaneous anthrax (eight confirmed and four suspected).²⁰

Although the overall number of individuals infected by this bioterrorist event was relatively low, the psychosocial-economic impact was exceptionally high. Several hundred postal and other facilities were tested for *B. anthracis* spore contamination, and public health authorities recommended antibiotic prophylaxis be initiated for approximately 32,000 persons.¹⁸ Additional indirect costs and effects are more difficult to quantify, including the number of persons self-initiating antibiotic treatment without an evident indication, lost production and wages, environmental and biological sample testing, decontamination efforts, and an international sense of unease.

Published estimates of tens of thousands of deaths from a military-style anthrax attack⁴³ depend on efficient BW dispersion. The technically easier anthrax letter has clearly proven itself to be a “weapon of mass disruption.” As predicted, the psychological impact far exceeded the actual medical emergency, and events with a modest number of medical patients are probably more likely than true mass-casualty BW incidents. On the other hand, prior assumptions regarding the clinical aspects of anthrax were not as reliable. The mortality rate among the 11 cases of inhalational anthrax was 45%, considerably lower than expected and probably because of earlier diagnosis, improved supportive care measures, and a wider choice of antibiotics, compared to historic controls. Presentation with fulminant illness, such as sepsis, still appears to be predictive of a fatal outcome, yet the initial phase of illness does not necessarily lead to death, if treated with appropriate antibiotics.^{6,42,46} Pleural effusions were the most common radiographic abnormality, rather than a widened mediastinum, and pulmonary parenchymal infiltrates were seen in seven patients, whereas earlier teaching had been that pneumonia does not commonly occur with inhalation anthrax.^{32,42}

Plague. *Yersinia pestis* is a Gram-negative bacillus (Fig. 133–4) responsible for more than 200 million human deaths and three major pandemics in recorded history.^{48,49} Naturally occurring plague is transmitted by flea vectors from rodent hosts, or by respiratory droplets from infected animals or humans. Bubonic plague could result from an intentional release of plague-infested fleas. Plague is a particularly frightening BW because it can be released as an aerosol to cause a fulminant communicable form of the disease for which no effective vaccine exists. Antibiotics must be initiated early after exposure because once symptoms develop, mortality is reportedly extremely high

FIGURE 133–4. Plague.

Clinical presentation. Plague occurs in three clinical forms: bubonic, septicemic, and pneumonic. Bubonic plague has an incubation period of 2 to 10 days followed by fever, malaise, and painful, enlarged regional lymph nodes called buboes. The inguinal nodes are most commonly affected, presumably because the legs are more prone to flea bites, although cervical or axillary buboes are more common in children⁵⁸ In the United States, 85% to 90% of human plague patients have the bubonic form, 10% to 15% have a primary septicemic form without lymphadenopathy, and about 1% present with pneumonic plague. Secondary septicemia occurs in 23% of patients presenting with bubonic plague⁴⁹ Various skin lesions at the site of inoculation (pustules, vesicles, eschars, or papules) occur in some patients, although the petechiae and ecchymoses that occur in advanced cases may resemble meningococcemia⁴⁸ Distal gangrene may occur from small artery thrombosis, explaining why plague pandemics are sometimes called the Black Death. If left untreated, bubonic plague carries a 60% mortality rate⁴⁸

Pneumonic plague is an infection of the lungs with *Y. pestis*. Between 5% and 15% of bubonic plague patients develop secondary pneumonic plague through septicemic spread of the organism.⁴⁹ Primary pneumonic plague occurs from inhalation of infected respiratory droplets or an intentionally disseminated BW aerosol. The incubation period of pneumonic plague is 2 to 3 days after inhalation. The onset of disease is acute and often fulminant. Patients develop fever, malaise, and cough productive of bloody sputum, rapidly progressing to dyspnea, stridor, cyanosis, and cardiorespiratory collapse. Plague pneumonia is almost always fatal unless treatment is begun within 24 hours of symptom onset.³⁰

Diagnosis and treatment. Plague can be diagnosed by various staining techniques, immunologic studies, or by culturing the organism from blood, sputum, or lymph node aspirates. When gram stained *Y. pestis* appears as a Gram-positive safety pin-shaped bipolar coccobacillus^{30,58} Chest radiographs in patients with pneumonic plague reveal patchy or consolidated bronchopneumonia. Leukocytosis with a left shift is common, as are markers of low-grade disseminated intravascular coagulation (DIC) and elevations of unconjugated bilirubin and hepatic aminotransferases³⁰

Antibiotic treatment options are similar to those for anthrax. In a mass-casualty setting or for postexposure prophylaxis, adults are treated with doxycycline 100 mg PO twice daily or ciprofloxacin 500 mg orally twice daily. Children receive doxycycline 2.2 mg/kg or ciprofloxacin 20 mg/kg, up to a maximum of the adult doses. Chloramphenicol 25 mg/kg orally four times daily is an alternative. The duration of treatment is 7 days for postexposure prophylaxis and 10 days for mass-casualty incidents.³⁹ Patients with pneumonic plague need to be isolated to prevent secondary cases. Respiratory droplet precautions are necessary in pneumonic plague until the patient has received antibiotics for 3 days.³⁰ In a contained-casualty setting, pneumonic plague is treated with parenteral streptomycin or gentamicin; alternative antibiotics include doxycycline, ciprofloxacin, and chloramphenicol.³⁹ A killed whole-cell vaccine effective against bubonic plague is available, but does not reliably protect against pneumonic plague in animal studies.^{48,50}

Tularemia. *Francisella tularensis* is a small, aerobic, Gram-negative coccobacillus (Fig. 133–5) weaponized by the United States and probably other countries as well. Tularemia occurs naturally as a zoonotic disease spread by blood-sucking arthropods or by direct contact with infected animal material. Tularemia in humans may occur in ulceroglandular or typhoidal forms, depending on the route of exposure. Ulceroglandular tularemia is more common, occurring after skin or mucous membrane exposure to infected animal blood or tissues. Patients develop a local ulcer with associated lymphadenopathy, fever, chills, headache, and malaise. Typhoidal tularemia presents with fever, prostration, and weight

loss without adenopathy. Exposure to aerosolized bacteria, as employed in BW, will most likely result in typhoidal tularemia with prominent respiratory symptoms such as a nonproductive cough and substernal chest discomfort. Diagnosing tularemia is often difficult, as the organism is hard to isolate by culture and the symptoms are nonspecific. Chest radiography may demonstrate infiltrates, mediastinal lymphadenopathy, or pleural effusions^{24,28,30,50}

FIGURE 133–5. Tularemia.

Antibiotic treatment options are similar to those for anthrax and plague. In mass-casualty settings, or for postexposure prophylaxis, adults are treated with doxycycline 100 mg twice daily or ciprofloxacin 500 mg PO twice daily for 14 days. Pediatric dosing for doxycycline is 2.2 mg/kg or ciprofloxacin 15 mg/kg (maximum = adult dose) twice daily. When dealing with a limited number of casualties, the preferred antibiotics are streptomycin 1 g intramuscularly (IM) twice daily, or gentamicin 5 mg/kg IM/IV once daily. Alternatives include parenteral doxycycline, chloramphenicol, and ciprofloxacin.²⁴

Brucellosis. Brucellosis could potentially be used as an incapacitating BW, because it causes disease with low mortality but significant morbidity. Brucellae (*Brucella melitensis*, *abortus suis*, and *canis*) are small, aerobic, Gram-negative coccobacilli (Fig. 133–6) that generally cause disease in ruminant livestock. Humans develop brucellosis by ingesting contaminated meat and dairy products or by aerosol transmission from infected animals. The United States weaponized *B. suis* and other countries are also believed to have developed *Brucella* bioweapons. Brucellosis commonly presents with nonspecific symptoms such as fever, chills, and malaise, with either an acute or insidious onset. Because brucellae are facultative intracellular organisms that localize in the lung, spleen, liver, central nervous system (CNS), bone marrow, and synovium, organ-specific signs and symptoms may occur. Diagnosis is made by serologic methods or culture. Because single-drug treatment often results in relapse, combined therapy is indicated. Treatments of choice (adult doses) are doxycycline 200 mg/day PO, plus rifampin 600 to 900 mg/day PO for 6 weeks, or doxycycline 200 mg/day PO for 6 weeks, with either streptomycin 15 mg/kg twice daily IM or gentamicin 1.5 mg/kg IM q8h for the first 10 days^{30,38,50}

FIGURE 133–6. *Brucella*.

Rickettsiae. Features of rickettsiae favoring their use as BW include environmental stability, aerosol transmission, persistence in infected hosts, low infectious dose, and high associated morbidity and mortality. Rickettsiae that have been weaponized include *Coxiella burnetti*, the causative organism of Q fever, and *Rickettsia prowazekii*, the causative organism of louseborne typhus. Release of *R. prowazekii* into a crowded louse-infested population might induce a typhus outbreak with rapid transmission and high mortality³

Q Fever. Q fever was first described in 1937, and was given its name—Q for “query”—because the causative organism was not then known. Q fever occurs naturally as a self-limited febrile, zoonotic disease contracted from domestic livestock. Q fever is now known to be caused by *Coxiella burnetti*, a unique rickettsialike organism that can persist on inanimate objects for weeks to months and can cause clinical disease with the inhalation of only a single organism. These features are of obvious benefit for use as a potential BW. After a 10- to 40-day incubation period, Q fever manifests as an undifferentiated febrile illness, with headache, fatigue, and myalgias. Patchy pulmonary infiltrates on chest radiography that resemble viral or atypical bacterial pneumonia occur in 50% of cases, although only half of patients have cough and even fewer have pleuritic chest pain. Uncommon complications include hepatitis, endocarditis, meningitis, encephalitis, and osteomyelitis. Patients are generally not critically ill, and the disease can last as long as 2 weeks. Treatment with antibiotics will shorten the course of acute Q fever and can prevent clinically evident disease when given during the incubation period. Tetracyclines are the mainstay of therapy, and either tetracycline 500 mg PO q6h or doxycycline 100 mg PO q12h should be given for 5 to 7 days^{11,30}

Viruses

Smallpox. Smallpox is caused by the variola virus, a large DNA orthopoxvirus (Fig. 133–7) with a host range limited to humans. Prior to global World Health Organization (WHO) efforts to eradicate naturally occurring smallpox by immunization, recurrent epidemics were common and the disease carried roughly a 30% fatality rate in unvaccinated populations^{37,47} Smallpox is highly contagious (Fig. 133–8). Outbreaks during the 1960s and 1970s in Europe often resulted in 10 to 20 secondary cases per index case. One German smallpox patient with a cough, isolated in a single room, infected persons on three floors of a hospital³⁷ However, the overwhelming majority of secondary infections occur among close family contacts, especially those sleeping in the same room or even in the same bed²⁶

FIGURE 133–7. Variola virus.

FIGURE 133–8. Smallpox rash.

In 1980, the United Nations' WHO certified that smallpox had been eradicated from the world, and recommended ceasing vaccinations and either destroying or transferring remaining stocks of variola virus to one of two designated biosafety level 4 facilities: the CDC in Atlanta or the Russian State Research Center of Virology and Biotechnology.⁹ All remaining known variola stocks were scheduled for destruction in 1999; however, before this was done, a WHO resolution called for a delay based on an Institute of Medicine report concluding that live virus should be retained to develop new antivirals or vaccines to protect against any potential future release of smallpox.⁶² The Soviet Union is known to have weaponized smallpox, and other countries are believed to maintain stocks of variola virus. In addition to the known stockpiles of smallpox vaccine, several types of new vaccines are being produced.^{56,70} Smallpox vaccination for military personnel was reinstated in 2002 and was made available for some civilians in 2003.^{21,22}

Pathophysiology. Transmission of smallpox typically occurs through inhalation of droplets or aerosols, but may also occur through contaminated fomites. The infectious dose is not known, but is probably only a few virions. After a 12-to 14-day incubation period, the patient develops fever, malaise, and prostration with headache and backache. Oropharyngeal lesions appear, shedding virus into the saliva. Two to three days after the onset of fever, a papular rash develops on the face and spreads to the extremities. The fever continues while the rash becomes vesicular and then pustular. Scabs form from the pustules and eventually separate, leaving pitted and hypopigmented scars. Deaths usually occur during the second week of the illness. Vaccination before exposure, or within 2 to 3 days after exposure, provides almost complete protection against smallpox. The disease most likely to be confused with smallpox is chickenpox (varicella). Although the individual lesions of smallpox and varicella are physically indistinguishable, the person infected with smallpox may still be differentiated clinically. The lesions of smallpox should all appear at the same stage of development (synchronous), whereas chickenpox lesions occur at varying stages (asynchronous). Smallpox lesions tend to be found in a centrifugal distribution (face and distal extremities), whereas chickenpox lesions are more centripetal and tend to appear first on the trunk.

Two antivirals commercially available in the United States, cidofovir and ribavirin, are effective in vitro against variola.⁵⁰ However, current evidence suggests that although cidofovir may prevent smallpox when given within 1 or 2 days of exposure, it is unlikely to be effective once symptoms develop.³⁷ Even a single case of smallpox should be considered a potential international health emergency and immediately reported to the appropriate public health authorities.

Smallpox vaccination. Rapid postexposure vaccination confers excellent protection against smallpox. The smallpox vaccine employs a live vaccinia virus (derived from cowpox vaccine) rather than the actual variola virus that causes smallpox. Although contracting smallpox from the vaccine is impossible, other adverse reactions may occur. The two most serious reactions are postvaccinal encephalitis and progressive vaccinia. Postvaccinal encephalitis occurs in about three cases per million primary vaccinees. Forty percent of cases are fatal, and some survivors are left with permanent neurologic sequelae. Progressive vaccinia can occur in immunosuppressed individuals and is treated with vaccinia immune globulin (VIG; Fig. 133–9).⁷⁰ Another historically common complication of smallpox vaccination was ocular vaccinia, which typically occurred among health care personnel administering vaccine when it was inadvertently placed in the eye. Ocular vaccinia is also treated with VIG. Because smallpox was eradicated before the emergence of HIV, there is limited clinical experience with smallpox vaccination in patients with AIDS who theoretically are at increased risk of progressive vaccinia.^{37,47} However, among 10 individuals with undiagnosed HIV at the time of recent smallpox vaccination, none developed complications.⁶⁵ Routine vaccination is contraindicated in the immunosuppressed, persons with a history or evidence of eczema and other chronic dermatitis, close household or sexual contacts of patients with these contraindications, and during pregnancy. Because the vaccine is a live virus, it can be transmitted from the vaccinee to close contacts. Thirty secondary and tertiary cases of vaccinia were reported resulting from recent US military vaccinations.²¹ The number of serious adverse events from modern smallpox vaccination is very low²²; however, rare cardiac complications not reported in previous decades were noted with the recent reinstitution of smallpox vaccination in the early 2000s. More than 1 million military vaccinations given by 2006 resulted in 120 cases of myopericarditis, while 21 cases of myopericarditis occurred among nearly 40,000 civilian vaccine recipients between 2002 and 2003.⁵⁶ The number of cardiac ischemic events among vaccinees was not significantly higher than age-matched controls. After a true exposure to variola, most authorities would agree that the only absolute contraindication to smallpox vaccination is significant impairment of systemic immunity. Concomitant administration of vaccinia immune globulin would be recommended for pregnant women and persons with eczema.⁴⁷

FIGURE 133–9. Progressive vaccinia.

Viral Hemorrhagic Fevers. Several taxonomically diverse RNA viruses produce acute febrile illnesses characterized by malaise, prostration, and increased vascular permeability that can result in bleeding manifestations in the more severely affected patients. Viral hemorrhagic fevers (VHFs) are all highly infectious by the aerosol route, making them candidates for use as BW. These include the viruses causing Lassa fever, dengue, yellow fever, Crimean-Congo hemorrhagic fever, and the Marburg, Ebola virus, and Hanta viruses. Hanta virus is endemic to North America; occasional natural epidemics of human infection occur, which may initially be difficult to differentiate from a BW release. Clinical features, such as the extent of renal, hepatic, and hematologic involvement, vary according to the specific virus, but they all carry the risk of secondary infection through droplet aerosols. Ribavirin is used for some VHFs, but supportive care is the mainstay of therapy^{7,30,41}

Viral Encephalitides. Three antigenically related α viruses of the Togaviridae family pose risks as BWs: western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Venezuelan equine encephalitis (VEE). Birds are the natural reservoir of these viruses, and natural outbreaks occur among equines and humans by mosquito transmission. Eastern equine encephalitis infections are the most severe in humans, with a 50% to 70% fatality rate and high incidence of neurologic sequelae among survivors. WEE is less neurologically invasive, and severe encephalitis from VEE is rare, except in children. Adults infected with VEE usually develop an acute, febrile, incapacitating disease with prolonged recovery. The equine encephalitides have many properties helpful for weaponization, in that they can be produced in large quantities, they are relatively stable and highly infectious to humans as aerosols, and a choice is available between lethal or incapacitating infections⁶³

Venezuelan equine encephalitis is considered the most likely BW threat among the viral encephalitides. After a 1-to 5-day incubation period, victims experience the sudden onset of malaise, myalgias, prostration, spiking fevers, rigors, severe headache, and photophobia. Nausea, vomiting, cough, sore throat, and diarrhea may follow. This acute phase lasts 24 to 72 hours. Between 0.5% and 4% of cases develop encephalitis, with meningismus, seizures, coma, and paralysis, which carries up to a 20% fatality rate. The diagnosis is usually established clinically, although the virus can sometimes be isolated from serum or from throat swabs, and serologic tests are available. The white blood cell count often shows a striking leukopenia and lymphopenia. Treatment is supportive. Person-to-person transmission can theoretically occur from droplet nuclei. Recovery takes 1 to 2 weeks.^{30,63}

Toxins

Several toxins derived from bacteria, plants, fungi, and algae could theoretically be used as BW, if produced in sufficient quantities. Because of their high potency, only small amounts would be needed to kill or incapacitate exposed victims. Fortunately, obstacles in manufacturing weaponizable amounts limit the number of toxins that are practical for use as biological weapons. Discussion here is limited to those toxins known or highly suspected to have been weaponized. Toxins themselves are not living organisms and therefore cannot reproduce; for this reason, they are arguably equivalent to chemical weapons. But because toxin weapons are derived from living organisms, they are categorized here as biological weapons.

Botulinum Toxin. Botulinum toxin has been developed as a biological weapon in the United States and other countries^{1,55,61,71} The two most likely means of employing botulism are by food contamination or by aerosol. Either method would result in the clinical syndrome of botulism ([Chap. 41](#)), characterized by multiple bulbar nerve palsies and a symmetric descending paralysis, ending in death from respiratory failure. Inhalational botulism from laboratory incidents

has occurred rarely in humans and has also been investigated in animal experiments⁵²

Ricin. Ricin is derived from the castor bean plant (*Ricinus communis*) and is the only biological toxin to exist naturally in more than microscopic quantities, comprising 1% to 5% of the beans by weight.⁸ Its easy accessibility, relative ease of preparation, and low cost may make ricin an attractive BW for terrorists or poor countries. Although ricin has never been used in battle, it has attracted the attention of domestic extremists and terrorists and has been used in politically motivated assassinations.^{2,23,29} Ricin is a glycoprotein lectin (or toxalbumin) composed of two protein chains linked by a disulfide bond. The B chain facilitates cell binding and entry of the A chain into cells. The A chain inhibits protein synthesis, inactivating eukaryotic ribosomes by removing an adenine residue from ribosomal RNA.²

Clinical toxicity from ricin will vary depending on the dose and route of exposure. Inhalation of aerosolized ricin results in increased alveolar-capillary permeability and airway necrosis following a latent phase of 4 to 8 hours. Ingestion causes gastrointestinal hemorrhage with necrosis of the liver, spleen, and kidney. Intramuscular administration produces severe local necrosis with extension into the lymphatics. In the absence of specific immunologic testing, differentiating ricin poisoning from sepsis may be difficult, because of the presence of leukocytosis and fever. Vaccination of laboratory animals with an investigational toxoid (a modified toxin that does not cause disease, but still induces an antibody response) is protective.²⁹

Staphylococcal Enterotoxin B. Staphylococcal enterotoxin B (SEB) is one of seven enterotoxins produced by *Staphylococcus aureus*. SEB is recognized as a “superantigen,” because of its profound activation of the immune system on exposure to even minute quantities. As a BW, SEB could be ingested through contaminated food or water, resulting in acute gastroenteritis identical to classic staphylococcal food poisoning. If inhaled as an aerosol, SEB produces fever, myalgias, and a pneumonitis after a 3-to 12-hour latent period. SEB inhalation can be fatal, but more often would simply be incapacitating for several days to weeks. Treatment is supportive.⁶⁷

Fungi and Other Fungal Toxins

Fungi may at first appear to be ideal BW, given their relative ease of handling, dissemination, and resistance of spores to physical stressors.¹² The only fungi to be included on lists of microbes with potential use as biological weapons are *Coccidioides* species, probably based on the high incidence of symptomatic infection in endemic areas. Nevertheless, the risk of serious disease is low, limiting the utility of *Coccidioides* as an effective weapon.^{12,57}

Fungal toxins considered to have potential use as BWs include trichothecene mycotoxins, aflatoxins, and amanita toxins. Although α -amanitin is extremely potent, water soluble, and heat stable, its use as a weapon would be limited by difficulties in mass production.⁵⁷ Aflatoxin would be ineffective on the battlefield, since its acute toxicity is uncertain and the carcinogenic potential is a delayed phenomenon.⁵ However, both of these toxins may still be effective as terror agents.

Trichothecene Mycotoxins. The trichothecene mycotoxins are low-molecular-weight (250–500 Da), nonvolatile compounds produced by filamentous fungi (molds) of various genera, including *Fusarium*, *Myrothecium*, *Phomopsis*, *Trichoderma*, *Tricothecium*, and *Stachybotrys*.^{5,68} Trichothecene mycotoxins are unusual among potential BW in that toxicity can occur with exposure to intact skin. Naturally occurring trichothecene toxicity results from ingesting contaminated grains or by inhaling toxin aerosolized from contaminated hay or cotton. Outbreaks of ingested trichothecene toxins result in a clinical syndrome called alimentary toxic aleukia, characterized by gastroenteritis, fevers, chills, bone marrow suppression with granulocytopenia, and secondary sepsis—a syndrome clinically similar to acute radiation poisoning. Survival beyond this stage is characterized by the development of GI and upper airway ulceration, and intradermal and mucosal hemorrhage. Trichothecene toxins are potent inhibitors of protein synthesis in eukaryotic cells, producing widespread cytotoxicity, particularly in rapidly proliferating tissues; different trichothecene toxins interfere with initiation, elongation, and termination stages of protein synthesis.⁵ Exposure to any mucosal surface results in severe irritation. Dermal exposure can produce inflammatory lesions lasting for 1 to 2 weeks, vesiculation, and, in higher doses, death.⁶⁸

Several reports from the 1970s and 1980s suggested that Soviet-supported forces were using trichothecene mycotoxins, particularly the toxin T-2 (Fig. 133–10), as BW. Aerosol and droplet clouds called Yellow Rain were associated with mass casualty incidents in Southeast Asia.⁶⁸ Such incidents would involve multiple routes of exposure, with skin deposition likely being the major site. Early symptoms included nausea, vomiting, weakness, dizziness, and ataxia. Diarrhea would then ensue, at first watery and then becoming bloody. Within 3 to 12 hours victims would develop dyspnea, cough, chest pain, sore mouths, bleeding gums, epistaxis, and hematemesis. Exposed skin areas would become intensely inflamed, with the appearance of vesicles, bullae, petechiae, ecchymoses, and frank necrosis.⁶⁸

FIGURE 133–10. T-2, a trichothecene mycotoxin.

Nonetheless, evidence that trichothecene mycotoxins were used as BWs was mostly circumstantial. Although T-2 toxin was found in victims' blood and urine, it was also found in samples from unexposed individuals, probably from baseline ingestion of contaminated foods. Environmental samples containing Yellow Rain droplets were inconsistently found to contain mycotoxins. Eyewitness accounts of Yellow Rain attacks varied widely (including various descriptions of the alleged agent's color), and, despite the large number of such attacks, no contaminated ordinance or dispersal device was ever recovered.⁶⁰ It was also discovered that Yellow Rain droplets were composed mostly of pollen grains. Supporters of the Yellow Rain as BW theory retorted that pollen grains would be an ideal carrier for biotoxins, given that their size is ideal for aerosolization. However, the pollen in Yellow Rain samples did not contain protein, similar to pollen that has been digested by bees. Further, the distribution of pollen species found in Yellow Rain was indistinguishable from the contents of feces of the Asian honeybee, and mass bee defecation resulting in showers of yellow droplets has been observed.⁶⁰ The Yellow Rain "bee feces theory" assumes that any mass-casualty incidents were from endemic disease outbreaks, other chemical or biological agents not yet identified, or a combination of both.

SUMMARY

- Many BWs are pathogenic bacteria, viruses, or toxins produced by microorganisms.
- BWs share many features with chemical weapons, including that the most effective method of dispersal to cause mass casualties will be via aerosolization. Disease after exposure to many BWs includes respiratory signs and symptoms.
- Victims of BWs exposure may present in a delayed fashion due to the incubation period of the disease. However, with proper identification of the agent, postexposure prophylaxis with antibiotics and/or vaccination may be possible.
- With typical universal precautions, ill victims from BWs exposure generally do not pose an infection risk to health care providers and others. Notable exceptions include pneumonic plague, smallpox, and the viral hemorrhagic fevers.

134 Radiation

Joseph G. Rella

Although the theory of atomism originated with the Greeks in the fifth century BC, it has been only a little more than a century that scientists could describe and measure atoms and the other particles of radiation. Today we utilize radiation and radionuclides for a vast array of purposes, ranging from mundane household uses such as smoke detection to powering satellites, cancer treatment, and examining the physical properties of individual molecules. Unfortunately, as our knowledge of how to use radiation has expanded so too has our awareness of radiation as a toxin. Indeed, for each of the last three editions of this text, there has been a significant radiation event that captured the world's attention and demonstrated clearly just how much more we need to know. The particles of radiation, their sources, and the mechanisms by which they pose a health risk are the subjects of the following discussion.

HISTORICAL EXPOSURES

Soon after x-rays were discovered in 1895, a deepening understanding of radiation and radionuclides led to their wider use and their resulting injuries. In the early days of radiation, exposures were small and of low energy, which nevertheless created injuries for a relatively small number of individuals. Clarence Dally was the first known radiation-induced death in 1904 following repeated exposures to Thomas Edison's early fluoroscopes. By 1927 nearly 100 women employed to create illuminated instrument dials became ill or died after exposure to radium-containing paint. Efforts to protect workers such as those by the British Roentgen Society were hampered by limitations on measurement of radiation despite the development in 1908 of the Geiger counter that could detect but not quantify radiation. Much later in 1984 and again in 1987, lack of proper remediation of closed radiation treatment centers led to scavengers releasing sources of ^{60}Co and ^{137}Cs , respectively. In the cobalt incident beginning in Juarez, Mexico, thousands of tiny metal pellets were spilled in a scrapyard and melted with other metals into table legs later shipped throughout Mexico and the United States. In the cesium incident in Goiânia, Brazil, scavengers were fascinated by the bluish glow of the material. Ultimately, 250 individuals were contaminated, 46 patients were treated with a chelator, and 4 died the month following the initial exposure with another dying several years afterward from radiation-induced injuries.

With the advent of the nuclear age, said to have begun with the first detonation of an atomic bomb in New Mexico in July 1945, suddenly the risks of radiation exposure grew to many thousands at once. Following the use of the two atomic bombs in Japan at the end of World War II, estimates of dead and injured for both cities were well over 200,000. Most of the deaths were from the bomb blast, but many thousands died from acute radiation syndrome (ARS) and others subsequently from radiation-induced cancers. In addition to the people of those cities who were victims of the bombs, many thousands of military personnel assigned to cleanup tasks or to attend nuclear weapons testing over the following 20 years were also exposed to radiation resulting from nuclear explosions. One relatively well-studied group, the British Nuclear Tests Veterans Association (BNTVA), found two-thirds of its study group died from neoplasms at ages 50 to 65 years, irrespective of the individual's age at the time of the witnessed explosion.

More recently in the post-nuclear testing era, large radiation incidents have occurred at the sites of nuclear reactors. In 1986, the Chernobyl nuclear reactor, built without a hard containment vessel, experienced a series of explosions releasing an enormous cloud of radioactive material. Thirty-one people died of ARS in the first few weeks following that event and an unknown number of millions potentially suffered other long-term sequelae in the surrounding geographic area.

And on March 11, 2011, a powerful earthquake off the east coast of Japan triggered a destructive tsunami that struck the Fukushima Daiichi nuclear power plant complex, knocking out its own electrical power and disabling the ability to cool its nuclear material. Over the following week, a series of explosions released an amount of radioactive material second only to the Chernobyl incident; however, no reports have suggested that anyone was injured from radiation exposure, although investigations are continuing.

In the realm of health care, radiologists of the early twentieth century used a thorium-containing contrast agent called Thorotrast in the initial development of angiography. Unfortunately, this xenobiotic accumulated in hepatic tissue resulting in malignancies and its eventual discontinuance in 1952. More recently the steadily increasing use of computed tomography (CT) has led to increased concerns over their safety and potential for stochastic effects. One retrospective study suggests there is a small but measurably increased risk for certain neoplasms in children following the accumulated radiation dose of several CT scans. This topic will be discussed in more detail later.

PRINCIPLES OF RADIOACTIVITY

Dating from the fifteenth century, radiation is defined as energy sent out in the form of waves or particles. Although considered by physicists as incomplete, the particle-wave theory remains a useful model by which to understand the toxic aspects of radiation. Despite the strong nuclear force that holds the basic building blocks of atoms together, many isotopes are unstable. Various influences such as quantum fluctuations and the weak nuclear force can tip the balance toward instability to transform an isotope. This process may be intentional, as with the criticality events in a nuclear reactor or nuclear bomb, but mainly occurs spontaneously in nature as the process called radioactive decay.

Radioactive Decay

In 1900, Marie Curie discovered that unstable nuclei decay or transform into more stable nuclei (daughters) via the emission of various particles or energy. Radioactive decay occurs mainly through five mechanisms: emission of γ -rays, α -particles, β -particles, positrons, or by capture of an electron. The emission of these various particles makes radioactive decay dangerous because these particles form ionizing radiation. Each radioisotope has a specific decay energy signature. That is, the emitted particles from a given radioisotope have known energies, which make identification of radiation sources possible.

The half-life ($t_{1/2}$) is the period of time it takes for a radioisotope to lose half of its radioactivity. Every radioisotope has a characteristic half-life, some lasting millionths of a second while others last billions of years. In every case, the activities of radioactive isotopes diminish exponentially with time (Table 134–1).

TABLE 134–1. Physical Properties of Radioisotopes

Isotope	Half-Life	Mode of Decay	Decay Energy (MeV)
Radioisotopes of Medical Examinations			
^{131}I	8 days	β^-	0.97
^{201}Tl	73 hours	EC	0.41
$^{99\text{m}}\text{Tc}$	6 hours	IT	0.14
^{133}Xe	5.27 days	β^-	0.43
^{67}Ga	78 hours	EC	1.00
^{18}F	109 months	β^- , EC	1.65
Military Radioisotopes			
^3H	12.26 years	β^-	0.02
^{235}U	7.1×10^8 years	α , SF	4.68
^{238}U	4.51×10^9 years	α , SF	4.27
^{210}Po	138 days	α	5.307
^{239}Pu	24,400 years	α , SF	5.24
^{241}Am	470 years	α , γ	5.14/0.02

EC = electron capture; IT = isomeric transition from upper to lower isomeric state; SF = spontaneous fission; MeV = megaelectron volts.

Photons are elementary particles that mediate electromagnetic radiation. Depending on their energy the radiation has different names ranging from extremely long radio waves to high-energy γ -rays.

X-rays and γ -rays are high-energy photons and are only distinguishable by their source. γ -Radiation is emitted by unstable atomic nuclei via radioactive decay and will have a fixed wavelength depending on the energy that formed it. X-rays come from atomic processes outside the nucleus. For example, an x-ray machine generates x-rays by accelerating electrons through a large voltage and colliding them into a metal target. The rapid deceleration of electrons in the target generates x-rays and in general, the higher the voltage, the greater the energy of the x-rays. Because of their nature, high-energy γ -and x-rays can penetrate several feet of insulating concrete.

β -Particles are also called electrons. They are emitted during β -decay from an unstable radionuclide. Positrons are positively charged electrons and may also be emitted during decay processes. Electrons have less penetrating ability than γ -radiation but may still pass several centimeters into human skin. β -Particles may also cause health problems chiefly through incorporation, or internalization into living organisms.

α -Particles are helium nuclei (two protons and two neutrons) stripped of their electrons and are emitted during α -decay. These particles are the most easily shielded of the emitted particles mentioned and may be stopped by a piece of paper, skin, or clothing. Unlike β -particles, α -particles principally cause health effects only when they are incorporated.

Neutrons are primarily released from nuclear processes although high-energy photon beams used in radiotherapy may also produce them. The natural decay of radionuclides does not include emission of neutrons, which is mainly a health hazard for workers in a nuclear power facility or victims of a nuclear explosion. Unique among the particles of radioactivity, when neutrons are stopped or captured they can cause a previously stable atom to become radioactive in a process known as neutron activation.

Cosmic rays complete the group of various kinds of radiation to which an individual may be exposed. Cosmic rays are streams of electrons, protons, and α -particles thought to emanate from stars and supernovas. They rain down on the earth from all directions only to give up their energy as they strike the nuclei of oxygen and nitrogen in the upper reaches of the Earth's atmosphere. By the time they reach the earth, the energy of cosmic radiation is reduced by several orders of magnitude. Traveling or living at altitude where the atmosphere shields relatively less cosmic radiation naturally means greater exposure to cosmic rays but in general is not considered a significant threat to humans.

Isotopes and nuclides are very closely related terms and most experts in the field use them interchangeably. An isotope is a set of nuclides with the same number of protons (eg, ^{123}I , ^{125}I , ^{127}I , ^{131}I). Nuclide is a more general term that may or may not be isotopes of a given element, such as fissile nuclides or primordial nuclides. Radioisotopes are isotopes that are radioactive, that is, they spontaneously decay and emit energy. Of the iodine nuclides listed previously, ^{123}I , ^{125}I , and ^{131}I are radionuclides. The nuclide ^{127}I is stable. Finally, radionuclides are simply nuclides that are radioactive.

Ionizing Radiation Versus Nonionizing Radiation

Ionizing radiation refers to any radiation with sufficient energy to disrupt an atom or molecule with which it impacts. In this interaction, an electron is removed or some other decay process occurs, leaving behind a changed atom. Depending on the specifics of the interaction, the chemical bonds become altered producing ions or highly reactive free radicals. Hydroxyl-free radicals, formed by ionizing water, are responsible for biochemical lesions that are the foundation of radiation toxicity.

The space between collisions of ionizing radiation and their target molecules varies with the particle type and its energy. A charged particle, such as an α particle, loses kinetic energy through a series of small energy transfers to other atomic electrons in the target medium, such as tissues. Most of the energy deposition occurs in the infratrack, a narrow region around the particle track extending about 10 atomic distances. The energy loss per unit length of particle track is called the linear energy transfer (LET), which is expressed in kiloelectron volts per micrometer (keV/ μm). Heavy charged particles, such as α -particles, are referred to as high-LET radiation, whereas x-rays, γ -rays, and fast electrons are low-LET radiation.

Because of its large size, collisions along the path of an α particle are clustered together, limiting its ability to penetrate tissue. By comparison, collisions along the path of γ -rays are spread out, increasing their ability to penetrate tissue. It is this ability to penetrate tissue and transfer energy that accounts for the relative dangers of the forms of radiation and tissue susceptibility.

For a source of radiation to pose a threat to tissue, the ionizing particle must be placed in close proximity to vital components of tissue to inflict damage. High-energy photons penetrate deeply and so pose a similar risk whether they come from an external source or from an incorporated source. As noted previously, α -particles have much more limited tissue penetration. Thus, α -emitters, radionuclides that radiate these particles, must first be incorporated to pose a threat to tissue. β -particles similarly have limited tissue penetration and usually are incorporated before damage may occur, although a large external exposure to β -emitters may cause serious cutaneous injury that could be life threatening, as discussed next.

Nonionizing radiation spans a wide spectrum of electromagnetic radiation frequencies. Generally, nonionizing radiation consists of relatively low-energy photons and is used safely in cell phone and television signal transmission, radar, microwaves, and magnetic fields that emanate from high-voltage electricity and metal detectors. Although these are all considered radiation in that they are all energies released from a source, these photons lack the necessary energy required to cause ionization and cellular damage.

Radiation Units of Measure

The amount of radiation to which an object is exposed, that is, the amount emitted from a source that falls on an object, is given in units called roentgens (R), a term that is now considered obsolete. A roentgen is a unit for measuring the quantity of γ -or x-radiation by measuring the amount of ionization produced in air. As an example, an individual standing at a given distance from the x-ray-generating tube of a particular x-ray machine is exposed, on the skin, to a particular number of roentgens of x-rays (Fig. 134-1).

FIGURE 134–1. The definitions associated with radiation. Both curie and becquerel describe a quantity of radionuclide in terms of the number of disintegrations rather than mass. Roentgens describes the amount of air ionized by either γ -or x-rays, which indirectly quantifies the amount of radiation in the air around a source. Rad and gray (Gy) describe the fraction of radiation that actually interacts with cellular material and potentially causes injury. Roentgen equivalent man (rem) and sievert (Sv) calculate the effective dose taking into account the different particles. For example, a 100 keV α -particle causes more damage to cellular material than a 100 keV β -particle.

Not all radiation to which an individual is exposed poses a risk for cellular damage. Much of the radiation passes through the body and causes no harm. Only the fraction that is absorbed by the tissue has a chance of causing cellular damage. The International System (SI) unit that describes absorbed radiation is the gray (Gy), which has replaced the rad (radiation-absorbed dose). One Gy equals 100 rad.

To measure the risk of biologic damage regardless of the type of radiation, the effective dose is given in sievert (Sv), which has replaced the rem (roentgen equivalent man). One Sv equals 100 rem. This calculation, known as dosimetry, takes into account the type of exposure (external or internal, partial or total), the particle or particles involved (eg, α , β , γ), and the radiosensitivity of the organ or organs exposed. The effective dose is calculated according to the following equation:

$$E = D \times W_R \times W_T,$$

where E is the dose in sieverts, D is the absorbed dose in gray, W_R is the radiation weighting factor, also called Q, and W_T is the tissue weighting factor indicating the radiosensitivity of each organ.

In 1910, the curie (Ci) became the unit describing the amount of radioactivity in a source. One curie equals 3.7×10^{10} disintegrations per second based on the decay of 1 g of radium. The curie was replaced by the SI unit the becquerel (Bq) where 1 Bq is equivalent to 1 disintegration per second. Thus, 1 Ci is equivalent to 3.7×10^{10} Bq. For example, following the Chernobyl incident, 1.2×10^{19} disintegrations per second of radioactive material was released into the atmosphere. By comparison, the radioactive source of ¹³⁷Cs in Goiânia contained 50.9×10^{12} Bq (13.7×10^5 mCi) of cesium. A thallium stress test uses 111×10^6 Bq (3 mCi) of ²⁰¹Tl, and the average indoor concentration of ²²²Rn in the United States is 55 Bq/m³ (14.8×10^{-6} mCi).

Protection From Radiation

Shielding refers to the process by which one may limit the amount of unwanted ionizing radiation in a given setting. Placing a specific material between a radiation source and a target will limit the amount of ionizing radiation that will interact with

the target. When a particle of ionizing radiation is incident on a material, there exists some probability that it will interact with the material and be attenuated. What happens as a result of this interaction is dependent upon several factors, including the type of particle, its energy, and the atomic number of the target material. The photoelectric effect for photons, Bremsstrahlung for β -particles, and elastic scattering for neutrons are several examples of specific interactions. The shielding equation below allows calculation of the efficacy of shielding.

$$I = I_0 e^{-\mu x},$$

where I is the radiation intensity after shielding, I_0 is the radiation intensity before shielding, μ is the linear attenuation coefficient, and x is the thickness material in centimeters. The linear attenuation coefficient is defined as the fraction of photons removed from the radiation field per centimeter of absorber through which it passes. Examples of shielding materials are Lucite, lead, and concrete.

Distance is an important safety factor in limiting radiation exposure. Because of their mass and electric charge, α - and β -particles have a high probability of interacting with matter, such as the atmosphere. The result is that these particles do not travel more than a few centimeters through air and, in general, moving a few feet from the source of this kind of radiation is enough protection by distance. However, x-rays and γ -rays are uncharged and have no rest mass, greatly reducing their probability of interacting with matter resulting in an unlimited range in space. Photon radiation that is emitted from a point source diverges from that source to cover an increasingly wider area. The intensity of this radiation follows the inverse square law:

$$\frac{I_1}{I_2} = \frac{(r_2)^2}{(r_1)^2},$$

where I_1 is the initial intensity, I_2 is the final intensity, r_1 is the initial distance from the source, and r_2 is the final distance from the source. For example, if the intensity of radiation 1 m from a source is 1 Gy, its intensity would be 0.11 Gy at 3 m from the source.

Time of exposure is another important safety factor in limiting radiation exposure. Obviously the longer a person is exposed to radiation the greater the exposure. The US federal and state regulations based on National Council on Radiation Protection and Measurement (NCRP) and US Food and Drug Administration (FDA) recommendations specify the limits of occupational exposure as well as exposure to patients designed to limit the potentially damaging effects of radiation.

Irradiation, Contamination, and Incorporation

An object is irradiated when it is exposed to ionizing radiation. One may be irradiated when handling radioactive isotopes, undergoing medical diagnostic imaging such as x-ray or CT, and rare exposures to criticality events. These sources of ionizing radiation generate particles that can penetrate tissue well and possibly cause tissue damage. Whole-body irradiation is one in which the entire body is exposed at once. However, more commonly shielding devices such as lead aprons, and collimation techniques used in radiotherapy limit the amount of exposed tissue to the intended target. The risk of tissue damage depends on the total amount of radiation and the tissue type because different tissue types have their own intrinsic resistance to radiation damage. An irradiated object does not become radioactive itself, unless exposed to neutrons and therefore irradiated individuals pose no risk to others.

The FDA approved irradiation of wheat and flour in 1963. They concluded from 40 years of study that irradiation is a safe and effective process for many foods to control bacteria such as *Escherichia coli*, *Salmonella* spp, and *Campylobacter* spp. Irradiation does not make food radioactive, compromise nutritional quality, or noticeably change the taste, texture, or appearance of food, as long as it is applied properly to a suitable product. Organizations that support irradiation of food include the American Medical Association (AMA), the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO).

Contamination occurs when a radioactive substance covers an object completely or in part. Several examples include a laboratory or industrial worker who unintentionally spills a radionuclide on clothing or skin or a victim of a radiologic dispersing device, a “dirty bomb,” in which a radionuclide is packaged with a conventional explosive and the resultant explosion disperses the radionuclide. In these similar cases, the source of radiation is the nuclide undergoing its normal decay process, and the individual is exposed to particles such as those mentioned in [Table 134–1](#). The risk for tissue damage from the radiation particles is usually quite low, assuming that the contamination is detected and appropriate measures for decontamination are instituted.

Incorporation occurs when a radionuclide is taken up by tissue via some route that permits the radionuclide to enter the body. This principle is used in many diagnostic and therapeutic procedures such as a thallium stress test, gallium scan, or thyroid ablation therapy. Depending on the dose and type of radionuclide, incorporation may lead to tissue damage, as was the situation for several people following the event at Goiânia.

EPIDEMIOLOGY

Everyone is exposed to radiation in one form or another each day (Table 134–2). In the United States, the estimated annual dose equivalent of radiation is now considered to be 6.2 mSv, a number revised sharply upward by the National Council on Radiation Protection and Measurements (NCRP) in 2009.²⁵ Although there are naturally occurring sources of radiation in the Earth's crust that make a significant contribution to our overall radiation exposure, the contribution from man-made sources of radiation, specifically medical exposures, has increased greatly over the last few decades, as discussed next.

TABLE 134–2. Annual Estimated Average Effective Dose Equivalent in the United States

Source	Dose ^a		
	mSv/year	mrem/year	% of total dose
Natural			
Cosmic	0.27	27	5
Internal	0.31	31	5
Radon ^b	2.29	233	37
Terrestrial	0.19	19	3
Subtotal	3.10	310	50
Man-Made			
Consumer products	0.12	12.4	2
Nuclear medicine	0.74	74.4	12
Occupational	< 0.01	0.62	0.1
Medical procedures	2.23	223.2	36
Subtotal	3.10	310	50
Total	6.20	620	100

^aAll doses are averages and contain some variability within the measurement. ^bAverage effective dose to bronchial epithelium.

mSv = millisieverts; mrem = millirem.

Data from Reference 25.

Exposures to man-made sources of radiation are not required to be reported to poison centers. Historically, those that have been reported have not resulted in significant morbidity. The American Association of Poison Control Centers National Poison Data System reported a total of 4203 exposures to radiation and radioactive isotopes over the last 14 years. Of the 267 exposures reported in 2010, 73% were unintentional, and 6% involved children younger than 6 years of age. There have been no deaths reported to poison centers from exposure to radioisotopes although three patients experienced a major effect, meaning either life-threatening or significant residual disability³ (Chap. 136).

Natural Sources of Radiation

A wide variety of natural sources expose humans on a daily basis to ionizing radiation. Terrestrial sources of radiation originate from radionuclides in the Earth's crust that move into the air and water. These primordial radionuclides, so named because their physical half-lives are comparable with the age of the Earth, include uranium, actinium, and thorium. Geographic areas vary regarding the content of these radionuclides.

Radon, a radioactive noble gas, accounts for most of the human exposure to radiation from natural sources. This gas, a natural decay product of uranium and thorium, enters homes and other buildings from the building materials themselves or through microscopic cracks in the building's structures. With a relatively short half-life of 3.82 days, ²²²Rn poses a health risk if decay occurs while in the respiratory space and one of its solid daughter isotopes deposits on respiratory tissue. These radon daughters emit α -particles as they decay and are the principle causes in the associated increased incidence of lung cancer in those exposed to radon. The risk of lung cancer is further increased in heavy smokers who additionally expose their lungs to as much as 200 mSv from ²¹⁰Po, a radon daughter that is naturally found in tobacco smoke. The US Environmental Protection Agency (EPA) has recommended household-level intervention when ambient radon concentrations exceed 147 Bq/m³ (4 pCi/L). Individuals can test their own homes for radon with either short-term (< 90 days) or long-term (> 90 days) commercially available measurement devices.

The second largest natural source of radiation originates from ingested radionuclides, of which ⁴⁰K, a naturally occurring isotope is the most abundant. Potassium is the seventh most abundant element in the earth's crust, and ⁴⁰K

represents about 0.012% of this naturally occurring element. With a half-life of 1.3 billion years, ⁴⁰K decays via β emission and electron capture. Since it is part of the environment, the average amount of ⁴⁰K in the body is about 3700 Bq (0.1 μ Ci), delivering about 0.18 and 0.14 mSv to soft tissue and bone, respectively. The lifetime cancer mortality risk has been calculated for ⁴⁰K to be 4 in 100,000 from external exposure compared with one in five from the group predicted to die of cancer from all other causes per the US average.

Man-Made Sources

The 2009 publication of the NCRPs sharply increased the estimated annual dose of radiation exposure due to man-made sources of radiation largely from the steeply rising use of CT (Table 134–3).²⁵ Evolving contemporaneously with the computer, CT technology has become extremely user friendly, contributing to the estimate that more than 70 million CT scans were performed in the United States during 2005 and 2006 compared with about 3 million scans in 1980, accounting for more than one-half of the man-made collective dose.^{2,23,38} Concern over potential cancer risks stemming from this new volume of exposure centers on children where doses are higher despite increasing practice to tailor scans to the size of the patient, and also because their relatively longer lives makes children more likely to manifest a slowly developing cancer. One retrospective study conducted in Great Britain through the National Health Service over 7 years examined data for more than 175,000 young patients each in two groups with certain leukemias and brain tumors.²⁷ Based on typical machine settings and estimated absorbed doses, this study found an increased relative risk of these cancers resulting from accumulated doses of just a few CT scans. Importantly, this was one of very few studies that did not rely on extrapolated data from atomic bomb survivors.²⁷

TABLE 134–3. Diagnostic Imaging Procedures: Type and Amount of Radionuclide or Radiation

<i>Test</i>	<i>Radionuclide</i>	<i>Amount MBq / mCi</i>		<i>Effective Dose mSv mrem</i>	
Thyroid scan	¹²³ I	25	0.68	1.9	191
Cardiac stress-rest test	²⁰¹ Tl	185	5	40.7	4070
Lung perfusion	^{99m} Tc	185	5	2.0	200
Lung ventilation	¹³³ Xe	740	20	0.5	50
Bone	^{99m} Tc	1110	30	6.3	630
Gallium	⁶⁷ Ga	150	4.05	15	1500
Tumor (PET)	¹⁸ F	740	20	14.1	1410
Plain Radiographs

Chest for pulmonary embolism				15	1500
Abdomen				8	800
Pelvis				6	600
Coronary angiography				16	1600

MBq = megabecquerel; mCi = millicuries; mSv = millisievert; mrem = millirem.

Data from Reference 22.

Overall use of other non-CT radiologic studies has increased greatly over the last decades as well. Estimates show 377 million radiologic procedures in the United States in 2006, not including more than 500 million dental radiologic examinations, although these examinations are not thought to contribute significantly to the overall accumulated dose. Nuclear medicine scans, particularly in the field of cardiology diagnostics, increased sharply as well and accounts for 4% of all radiologic procedures and 26% of the total collective dose.²¹

Nuclear Occupational Exposure. Estimates of the annual number of workers occupationally exposed to radiation worldwide are several million.³³ On average, those occupations with the highest exposures (about 4 mSv/year) are uranium miners and millers. Overall, as of 1994 the average annual effective dose to monitored workers in the nuclear fuel industry dropped from 4.1 to 1.8 mSv, mainly due to a large decline in underground mining. Despite the many factors that play a role in occupational exposure at more than 1200 nuclear reactors worldwide, the estimated annual effective dose to measurably exposed workers fell to 2.7 mSv.

Medical occupational exposure principally includes physicians, nurses, x-ray technologists, and laboratory workers who receive an additional annual effective dose of about 0.5 mSv, which is down from about 1 mSv 25 years ago, possibly due to efforts to improve protection practices. Exposures have been studied in emergency physicians, orthopedists, and interventional cardiologists.^{15,35} Each of these fields uses different modalities of radiation, which pose different risks to the individual performing the procedure. Although older studies suffered from various limitations, small sample sizes, and unreported compliance with recording devices, several recent studies support the older conclusions that while physicians in the emergency department are exposed to radiation from conventional radiography the doses are typically on the order of 0.5 mSv (50 mrem) per year. These doses are well below the upper limits of exposure set by the Nuclear Regulatory Commission (NRC).^{9,11,12,37} Future exposures may actually decline due to increased use of CT for trauma patients in which physicians are in the control room while scanning is in progress. Thus, although the number of CT scans performed continues to rise, the radiation exposure to staff remains low due to collimation and low scatter, as well as proper shielding in properly designed facilities.

Fluoroscopy constitutes less than 10% of all examinations in the United States but remains the largest source of occupational exposure in medicine. Studies of physician exposure to radiation by fluoroscopy used in various procedures including interventional cardiology, nephrolithotomy, vertebroplasty, extremity nailing, biliary tract, and others report effective doses ranging from 1 to 100 μ Sv (0.1–10 mrem). Depending on the procedure, doses to the hands, brain, lens of the eye, and thyroid could be much higher placing physicians at greater risk of stochastic effects than is suggested by the effective dose.^{15,35} Estimated whole-body exposures to these procedures were considered not to exceed the limits established by the Occupational Safety and Health Administration (OSHA) of 50 mSv per year. Although the likelihood of exceeding established radiation limits is low regardless of the procedure, and even assuming a reasonable increase in the number of procedures performed, appropriate shielding and safety training are emphasized to minimize the risk of exposure.

Worldwide, nearly 500,000 workers are monitored for exposures during dental x-ray, but the annual effective dose averaged over 5 years has declined to 0.05 mSv. Well over 100 million nuclear medicine procedures are performed annually in the laboratory, but the exposures of this type are quite small.²¹

Depleted uranium (DU) is used by the US military and by several other governments. Uranium ore mined from the earth is about 99% ^{238}U and 1% ^{235}U . Enrichment involves separating the isotopes—for example, via high-speed gas centrifuge—so that ^{235}U can be used as nuclear fuel and the leftover ^{238}U can be used in munitions. Consequently, although DU is radioactive, it is 40% less so than naturally occurring uranium. External exposure to solid ^{238}U is considered to be negligible although currently many studies are investigating the potential link between DU and the incidence of leukemias, other cancers, and birth defects.¹ The Depleted Uranium Follow-Up Program has surveyed exposed veterans since 1994 has not discovered any consistent, clinically significant differences in uranium-health parameters, which includes hematopoiesis, neuroendocrine, and renal function.^{20,32}

EXPOSURE LIMITS

The NRC has established the “Standards for Protection against Radiation,” which regulates radiation exposures using a twofold system of dose limitation: doses to individuals shall not exceed limits established by the NRC, and all exposures shall be kept as low as reasonably achievable (ALARA). The total effective dose equivalent may not exceed 50 mSv/year to reduce the risk of stochastic effects (see Stochastic vs. Deterministic Effects of Radiation). The dose to the fetus of a pregnant radiation worker may not exceed 5 mSv over 9 months and should not substantially exceed 0.5 mSv in any 1 month.

REGULATION AND REPORTING

The use of ionizing radiation, radiation sources, and the byproducts of nuclear energy are among the most heavily regulated

processes worldwide. Regulations for medical use of radiation derive from multiple international and national organizations. Among the international groups are the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), International Commission on Radiological Protection (ICRP), Biological Effects of Ionizing Radiation (BEIR) Committee, International Commission on Radiological Units and Measurements (ICRU), Radiation Effects Research Foundation (RERF), and International Radiation Protection Association (IRPA). Since international organizations do not have the authority to enforce their recommendations worldwide, most countries have their own regulatory groups that cooperate internationally. In the United States, the NCRP reviews recommendations from the ICRP and makes recommendations. The NCRP issues BEIR reports that have direct standards for ionizing radiation use. For medical imaging standards, recommendations from the NCRP are considered to be guidelines with which all radiology departments must comply. The goal is to foster a radiation protection program that prevents deterministic effects. Additionally, the Conference of Radiation Control Program Directors (CRCPD) suggests state regulations for control of radiation.

National regulatory agencies include the NRC, EPA, OSHA, and the FDA. The NRC also runs an Agreement State Program, which is where states have had the authority to regulate transferred to them by the NRC. The US Department of Transportation (DOT) regulates transport of hazardous materials including radioactive material.

The NRC, the EPA, and many state governments share the responsibility of licensing and regulating radionuclides in the United States. The Oak Ridge Institute for Science and Education's (ORISE) supports the NRC by maintaining the NRC's Web site for Radiation Exposure Information and Reporting System (REIRS) and the database of radiation exposure from NRC licensees (<http://www.reirs.com/>). Individual states regulate radioactive substances that occur naturally or are produced by machines, such as linear accelerators or cyclotrons. The EPA oversees the general area of environmental monitoring of radiation. The FDA regulates the design and manufacture of electronic products, inspects diagnostic x-ray equipment, and establishes specific operational standards for x-ray equipment. The NRC regulates medical, academic, and industrial uses of nuclear materials generated by or from a nuclear reactor. OSHA regulates occupational exposure to radiation, oversees regulations for training programs and "right to know" regulations.

ORISE's Radiation Emergency Assistance Center/Training Site (REAC/TS) and the International Atomic Energy Agency (IAEA) both maintain radiation incident registries that track US and foreign radiation incidents. Information for the REAC/TS registries is gathered from many sources, including the WHO Radiation Emergency Medical Preparedness and Assistance (REMPAN), IEAE, state health departments, and medical and health physics literature.

PATHOPHYSIOLOGY

Ionizing radiation causes damage to tissue by several mechanisms called direct or indirect effects. Direct effects are when particles physically damage the DNA in a cell, which can occur at the sugar phosphate backbone, hydrogen bonds, or base molecules. Although any type of radiation may cause this damage, high LET radiation is more likely to cause direct effects owing to its greater probability of interacting with DNA. When this kind of damage occurs a mutation may arise, which may then result in alteration of a germ line, development of a neoplasm, or cell death. The risk of these consequences overall, however, is low because of the relative paucity of DNA within a cell, the even smaller percentage of active DNA within a given cell, and the ability of DNA to repair itself.

While DNA represents a low probability target for radiation, the rest of the cell media represents a higher probability target. Indirect effects are when radiation impacts a molecule and creates a reactive species, which then chemically reacts with organic molecules in cells altering their structure or function. These radiation-induced ions are unstable, however, and usually convert to free radicals. Water, which is in great abundance within cells may transform into a hydroxyl radical ($\text{OH}\cdot$) following interaction with incident radiation. The hydroxyl radical diffuses only a short distance through the cell because of its highly reactive nature and itself causes molecular damage. Indirect effects are predominantly caused by low LET radiation (x-rays, γ -rays, and fast electrons).

The bystander effect refers to cellular damage in unirradiated cells that neighbor irradiated cells. As early as the 1940s, there were reports of inactivation of cells by ionization of the surrounding medium. Recently, the use of a single-particle microbeam (a device that can fire a predefined exact number of α -particles through a particular cell nucleus) demonstrated that cultured cells that were not hit by radiation showed increased chromosome damage, rearrangement, and rate of death. In one experiment, when 10% of cells on a dish were exposed to two or more α -particles, the resulting frequency of induced oncogenic transformation was indistinguishable from that when all the cells on the dish were exposed to the same number of α -particles.²⁴ Studies demonstrate the bystander effect for proton beams, x-rays, and low LET radiation.²⁸

Genomic instability is a single mutation followed by a cascade of further mutations altering the fidelity of genomic replication. This modification can be found in cell progeny many generations after irradiation and may have unpredictable outcomes in succeeding generations. Although many hypotheses have been suggested, it appears most likely that the instability is due to irreversible regulatory change in the network of cellular gene products.^{10,13,19}

Although any molecule may be damaged in a variety of ways that may lead to cell injury of varying severity, double-stranded breaks in DNA are the type of damage most likely to cause chromosomal aberrations or cell death. The

radiosensitivity of the cell is directly related to its rate of proliferation and inversely related to its degree of differentiation.

Thousands of these types of lesions occur daily in the human body. There are several mechanisms by which the body can affect its own repair, which forms the basis of fractionated radiation therapy, taking advantage of less efficient repair mechanisms of tumor cells. However, there is evidence that DNA damage induced by radiation is chemically different and more complex from DNA damage that occurs spontaneously, which contributes to a higher rate of mutation than that resulting from spontaneous damage. Dose-response relationships for mutation are approximately linear down to about 25 mGy, the statistical limit of these studies. Although repair mechanisms reduce substantially the radiation risk of mutation, there is no evidence yet that these mechanisms eliminate those risks at low doses, although some question this conclusion.¹⁶

STOCHASTIC VERSUS DETERMINISTIC EFFECTS OF RADIATION

The radiation damage just described has two consequential results: it kills cells or it alters cells and causes cancer. Injuries that do not require a threshold limit to be exceeded include mutagenic and carcinogenic changes to individual cells where DNA is the critical and ultimate target. This is the stochastic effect of radiation. Theoretically, there is no dose of radiation too small to have the potential of causing cancer in an exposed individual.

Whereas the stochastic effects of radiation may follow less severe exposures, the deterministic effects of radiation usually follow a large whole-body exposure, such as a Chernobyl-type event. In terms of cell death, a relatively large number of cells of an organ system must be killed before an effect becomes clinically evident. This number of killed cells constitutes a threshold limit that must be exceeded, and this is what is known as the deterministic or nonstochastic effects of radiation.

To illustrate the differences between stochastic and nonstochastic effects, consider a single α particle from ^{210}Po incorporated following exposure in a radon-contaminated household may impact an active segment of DNA in a patient's respiratory tract, ultimately giving rise to a cancer—the stochastic effect. In Tokaimura, Japan, following exposure to a criticality event, the most severely injured worker received 17 Sv of neutron- and γ -radiation and experienced so much cell death across so many systems in his body that he died well before any injured yet surviving cells could develop into a cancer—the deterministic effect.

ACUTE RADIATION SYNDROME

The US Army Medical Corps first described ARS in 1946 when victims of the explosions at Hiroshima and Nagasaki were admitted for treatment at Osaka University Hospital.¹⁴ Understanding the features of ARS is essential for managing a patient who is exposed to massive whole-body irradiation, generally considered to be 1 Gy (160 times the average annual exposure) or more. In many cases, a reliable estimate of the radiation dose is difficult making it more practical to focus on the clinical features of radiation injury and their prognostic utility.

ARS involves a sequence of events that varies with the severity of the exposure.³⁶ Generally, more severe exposures lead to more rapid onset of symptoms and more severe clinical features. Four classic clinical stages are described, which begin with the early prodromal stage of nausea and vomiting. These symptoms begin anywhere from hours to days postexposure. Although the time to onset postexposure is inversely proportional to the dose received, the duration of the prodromal phase is directly proportional to the dose. That is, the greater the dose received, the more rapid the onset of symptoms, and the longer their duration, except in cases in which death follows rapidly. The latent period follows next as an apparent improvement of symptoms, during which time the patient appears to have recovered and has no clinically apparent difficulties. The duration of this stage is inversely related to dose and may last from several days to several weeks. The third stage usually begins in the third to fifth week after exposure and consists of manifest illness described in subsequent paragraphs. If the patient survives this stage, recovery, the fourth stage, is likely, but may take weeks to months before it is completed. Those exposed to supralethal amounts of radiation may experience all the phases in a few hours prior to a rapid death.

These four stages describe the clinical manifestations that may be observed as a result of massive exposure, but the various systems of the body manifest their own injuries, which constitute several subsyndromes. These subsyndromes are not mutually exclusive of one another and may overlap as cell death or damage progresses. Once these subsyndromes are manifest, they may be irreversible.

The cerebrovascular syndrome describes the manifestations of injury to the central nervous system following massive irradiation. This syndrome, following exposure to doses of about 15 to 20 Gy or greater, is characterized by rapid or immediate onset of hyperthermia, ataxia, loss of motor control, apathy, lethargy, cardiovascular shock, and seizures. The mechanism of this injury may be a combination of radiation-induced vascular lesions and free radical-induced neuronal death and cerebral edema.

Despite autopsy evidence of some radiation-induced inflammatory changes to the heart, animal experiments demonstrate that the heart is relatively resistant to high doses of radiation. Cardiovascular shock is more likely because of systemic

vascular damage, which may later compound shock resulting from other subsyndromes should the patient survive to that point. A “vascular radiation subsyndrome” might be considered to help explain the hemodynamic changes a patient experiences following a massive dose of radiation.

The pulmonary system is not spared injury from irradiation. Pneumonitis may occur within 1 to 3 months following a dose of 6 to 10 Gy. This may lead to respiratory failure, pulmonary fibrosis, or cor pulmonale months to years later.

The gastrointestinal syndrome begins following an exposure to about 6 Gy or more when gastrointestinal mucosal cell injury and death occur. Findings and effects include anorexia, nausea, vomiting, and diarrhea. As the mucosal lining is sloughed, there is persistent bloody diarrhea, hypersecretion of cellular fluids into the lumen, and a loss of peristalsis, which may progress to abdominal distension and dehydration. Destruction of the mucosal lining allows for colonization by enteric organisms with ensuing sepsis.

The hematologic changes that occur following an exposure to about 1 Gy or greater are called the hematopoietic syndrome. Hematopoietic stem cells are highly radiosensitive, in contrast to the more mature erythrocytes and platelets. Lymphocytes are also radiosensitive and can die quickly from cell lysis following an exposure. This contrasts with granulocytes, which endure radiation better. In addition to stem cell death and white cell depletion with immunodeficiency, platelets are consumed in gingival and gastrointestinal microhemorrhages. The main effect of radiation-induced hematopoietic syndrome is pancytopenia leading to death from sepsis complicated by hemorrhage. The lymphocyte nadir typically occurs 8 to 30 days postexposure, with higher doses achieving earlier nadir.

The cutaneous syndrome, a local radiation injury, may develop early after exposure or may take years to manifest fully. Target cells include all layers including epidermis, hair follicle canals, and subcutaneous tissue. Signs and symptoms may include bullae, blisters, hair loss, pruritus, ulceration, and onycholysis. Skin injury ranges from epilation beginning at doses of 3 Gy to moist desquamation at about 15 Gy, to necrosis at 50+ Gy.

DOSE ESTIMATION

Determining the dose received by an individual who was irradiated is important in providing appropriate therapy and establishing a prognosis. Estimating the dose received is difficult for a number of reasons, such as the absence of a radiation-monitoring device, exposure to radiation of mixed form (such as γ and neutron radiation), and partial shielding of various body parts.

Biodosimetry is the use of physiological, chemical, or biological markers to reconstruct radiation doses to individuals or populations. Today there are numerous tools available on the Internet to assist with dosimetry, including the Biological Assessment Tool available at the Armed Forces Radiobiology Research Institute’s Web site, guidelines from the International Atomic Energy Agency, and the Radiation Emergency Medical Management Web site. Key elements of dose estimation include time to onset of vomiting, lymphocyte depletion kinetics, and chromosomal assays.

Postincident vomiting can be a sign of the ARS prodrome. Unfortunately, the incidence of vomiting in patients with significant exposure is not 100% and may also be a sign of psychological stress contributing to inaccurate estimation, especially at low doses. Fortunately, for the purposes of dosimetry lymphopenia is common following an exposure to 1 Gy or more. The observed predictability of lymphopenia has led to the development of several models for biodosimetry. Although dosimetry models are validated and account for potential modifiers such as trauma or burns, discrepancies between models suggest that more than one element of dosimetry be used whenever possible. Combining emesis and lymphopenia in a triage tool developed at REAC/TS helps to distinguish patients exposed to high dose from those exposed to less than 1 Gy.

$$T = N/L + E,$$

where T is the triage score, N/E is the neutrophil/lymphocyte ratio, and E is whether emesis has occurred. E equals 0 if no emesis and E equals 2 if emesis. Based on cases from the REAC/TS registry, for times longer than 4 hours postevent, if T is greater than 3.7, then the patient is deemed at risk to high dose exposure and should receive a further evaluation.

The broad ranges of radiation doses that correlate with lymphocyte count are described in the classic Andrews nomogram of 1965. Again, using historic data from exposed patients, a lymphocyte depletion constant was calculated using the equation

$$L(t) = L_0 e^{-K(D)t},$$

where L(t) is the lymphocyte count at time t, L_0 is the lymphocyte count prior to the exposure—the population mean taken as 2.45×10^9 cells/L—K is the rate constant for a given dose of radiation, and D is the dose of radiation. Solving for K(D) will allow for an accurate estimate of a rapidly delivered, whole-body exposure.

Although there are still other methods of biodosimetry, such as interphase aberrations assessment and electron spin resonance of dental enamel, measurement of chromosomal aberrations has become the gold standard. Introduced in 1966,

this technique analyzes the number of dicentric chromosomes that occur following a whole-body exposure to radiation. An exposure to radiation can cause breakage of the DNA molecule in two nonhomologous chromosomes and produce “sticky ends” that recombine end-to-end. In metaphase, these appear as a single chromosome with two centromeres and are called dicentric. The number of dicentrics in lymphocytes correlates reliably with a given dose of radiation. This assay conforms to International Organization for Standardization (ISO) but suffers from several drawbacks including reduction of cells for assay in the setting of proliferative cell death, and migration of lymphocytes into tissue and the lymphatic system, both limiting the time available to perform an accurate test. Other methods include the cytokinesis-block micronucleus (CBMN) assay where other unstable aberrations form but disappear over time, and premature chromosome condensation assay where chromosomes are stimulated to condense prematurely for evaluation of radiation-induced damage. This assay can detect higher doses than dicentric analysis but has yet to be validated and standardized. The translocation assay uses fluorescence in situ hybridization (FISH) chromosome-painting technique and is used primarily for estimating doses of historical exposures. Unlike dicentrics, complete translocations persist in cell Division and enable dose estimation over years following exposure. In fact, when this technique was employed to evaluate the radiation dose experienced by clean-up workers at Chernobyl, the authors concluded that it was likely that recorded doses for these cleanup workers overestimate their average bone marrow doses, perhaps substantially.¹⁷ Unfortunately, these techniques are not widely available, require incubation times of 48 to 72 hours, and cannot assess for doses greater than 5 Gy.

CARCINOGENESIS

Radiation was recognized as a carcinogen soon after it was initially discovered in 1895. Following decades of research including animal models, epidemiologic studies, and the life-span studies of Japanese nuclear bomb survivors, radiation was shown to be a “universal carcinogen” able to induce tumor in nearly every tissue type in nearly every species at all ages. In fact, radiation’s ability to induce cancer is so well established that the last three decades of research has used radiation-induced tumors to focus on DNA damage and repair mechanisms.

Double-stranded breaks are the biologically important lesion for inducing tumors. Although radiation can induce point mutations, it can also induce deletions, sometimes of an entire gene. Research on transcription-coupled repair, where the transcribed strands of expressed genes are more rapidly repaired than the rest of the genome, were shown to be repaired most often by an illegitimate recombination process that is error-prone. This loss of heterozygosity suggests that radiation-induced carcinogenesis may more likely result from inactivation of a tumor suppressor gene than activation of a proto-oncogene.¹⁸

COMMONLY ENCOUNTERED RADIONUCLIDES

Most patients who come to medical attention are not exposed to large, whole-body irradiation but rather to small spills in the laboratory or inadvertent exposures from one of many products that are commercially available. With the notable exception of a well-known case of massive americium contamination in Oak Ridge, Tennessee, and the cesium exposure in Goiânia, Brazil, the vast majority of these types of cases are not reported in the medical literature.

Americium (symbol Am, atomic number 95, and atomic weight 243) was discovered in 1944 in Chicago during the Manhattan Project. Its most stable nuclide, ²⁴³Am, has a half-life of more than 7500 years, although ²⁴¹Am, with a half-life of 470 years, was the first americium isotope to be isolated. It decays by α and γ emission and will accumulate in bone if incorporated. It is used to test machinery integrity, glass thickness, and in smoke detectors (about 0.26 μ g per detector), where it ionizes the air between two electrodes and generates an electric current that soot may impede. α -Particles from these detectors are easily absorbed within a few centimeters of the surrounding air and pose little risk. One gram of americium dioxide provides enough americium for more than 5000 smoke detectors. In 1976, a worker at the Hanford Plutonium Finishing Plant suffered a large ²⁴¹Am contamination in an explosion at the site. The patient was contaminated with 100 g or 70 MBq (500,000 smoke detectors’ worth) in the explosion. He was treated with long-term pentetic acid (DTPA) and, despite some leukopenia from the radiation, he survived for 11 years before dying from unrelated cardiac disease.

Cesium (symbol Cs, atomic number 55, and atomic weight 132) was discovered by Bunsen in 1860. It decays by β and γ emissions and tends to follow the potassium cycle in nature. It is used as a radiation source in radiation therapy and as a radionuclide source for atomic clocks. Cesium, the radionuclide of the Goiânia incident, comes in the form of a powder, which would make dispersal relatively easy if used in a dirty bomb. Insoluble Prussian blue is the FDA-approved chelator for patients contaminated with cesium (Antidotes in Depth: A28).

Iodine (symbol I, atomic number 53, and atomic weight 126.9) was discovered by Courtois in 1811. Of the 23 isotopes of iodine ¹²⁷I is the only one that is stable. ¹²⁹I and ¹³¹I are fission products that may be released into the environment during an event. These isotopes will accumulate in thyroid tissue if incorporated and can cause local damage to thyroid tissue. It is this potential for incorporation that prophylaxis with potassium iodide (KI) is indicated in the event of a large exposure.

Polonium (symbol Po, atomic number 84, and atomic weights range from 192 to 218) was discovered by Marie Curie

while searching for the cause of radioactivity of pitchblende (uranium ore). It was named after her native country of Poland. Po has 27 isotopes, the most isotopes of all the elements and all are radioactive. Po is a very rarely occurring natural element where only 100 µg is found in a ton of uranium ore. Po is chiefly manufactured by bombarding ^{210}Bi with neutrons in nuclear reactors, and it exhibits several properties that make it extremely dangerous. The short half-life of ^{210}Po and high specific activity of 4490 Ci/g means it emits a great deal of high-energy α -particles (5.3 MeV) that produce 140 W/g. For example, a capsule containing 500 mg of ^{210}Po reaches a temperature of 932°F (500°C). It also demonstrates a high volatility where 50% vaporizes in 45 hours at 131°F (55°C) and can contaminate a relatively large area even when left alone. Although only a small fraction of absorbed ^{210}Po accumulates in tissue, cumulative doses of radiation can lead to organ systems failure and death. Animal data estimate an LD₅₀ of 1.3 MBq/kg, and that various mammalian species die within 20 days following ingestion of 1 to 3 GBq. Because of the extreme specific activity of ^{210}Po , this corresponds to a dose of about 0.01 µg/kg. Currently there are no specific chelating agents for ^{210}Po . While there are limited data regarding the effects of ^{210}Po on humans, Alexander Litvinenko's death within 22 days of his poisoning with polonium is similar to animal survival data.

Radon (symbol Rn, atomic number 86, and atomic weights range from 204 to 224) was discovered in 1900 by Dorn and is the heaviest noble gas. ^{222}Rn decays by α and γ emissions. Exposure of radon gas to the pulmonary epithelium is associated with an increased incidence of lung cancer in both uranium miners and in those who dwell in residences with increased concentrations of radon. Damage to bronchial epithelium results from the α emissions of radon and radiation from radon daughters that precipitate as solids and remain in the lungs. Good enclosed space ventilation, abstinence from cigarette smoking, and monitoring of radon concentrations help to minimize this risk.

Technetium (symbol Tc, atomic number 43, and atomic weight 98.9) was discovered in 1937 and was the first element to be produced artificially. Unusual among the lighter elements, Tc has no stable isotopes and is therefore found on earth as a product of spontaneous uranium fission. The majority of technetium is extracted from nuclear fuel rods and is used in nuclear medicine for imaging. $^{99\text{m}}\text{Tc}$ (the m is for metastable referring to an intermediate energy state) emits γ -rays of similar energy to diagnostic x-rays for easy detection and has a brief half-life of 6 hours. The daughter isotope, ^{99}Tc , has a half-life of 2.1×10^5 years and allows the isotope to be eliminated before it decays. Most human contact with Tc is in medical scans where Tc has a biological half-life of about one day. There are no reports of adverse effects resulting from overdose with Tc, and no specific therapy is recommended in that event.

Thallium (symbol Tl, atomic number 81, and atomic weight 204) was discovered by Crookes in 1861. ^{201}Tl is used for cardiac imaging, has a half-life of 73 hours, and decays by electron capture and γ emission. Pharmaceutical ^{201}Tl is created in a cyclotron by bombarding thallium with protons creating ^{201}Pb and is shipped in this form, which decays into ^{201}Tl . Since the radioactive decay process is continual, it is recommended to administer the ^{201}Tl close to its calibration time to minimize the presence and effects of other radionuclidic contaminants. Chelation can be accomplished with Prussian blue (Antidotes in Depth: A28).

Tritium is an isotope of hydrogen whose nucleus contains one proton and two neutrons, and its symbol is ^3H . Tritium decays by β activity and is used in basic science research as a radioactive label, for luminous dials, and self-powered exit signs, which may contain as much as 9.3×10^{11} Bq (25Ci). Tritium has a half-life of 12.3 years. Tritium emits very weak radiation in the form of 18.6 KeV β -particles, which are easily stopped by thin layers of material, and is safe for glow-in-the-dark watches. Tritium is not absorbed as a hydrogen gas, although, when in contact with oxygen it forms tritiated water, which can be absorbed via inhalation or transdermally. The estimated LD₅₀ is 3.7×10^{11} Bq (10 Ci) given its extreme specific activity of 9649 Ci/g. When absorbed as tritiated water, tritium tends to follow the water cycle in humans, providing a whole-body dose if incorporated. However, its biologic half-life is 10 to 12 days, which can be decreased by increasing urine output, greatly limiting its potential toxicity.

MANAGEMENT

Initial Assessment and Early Triage

The initial management of patients exposed to radiation will depend on a number of different factors, including the amount of radiation in the exposure and the number of casualties in the event. Small-scale exposures to radiation still require at least a brief evaluation for burns and trauma, depending on the circumstances surrounding the nature of the exposure. Calls to the poison center from a residence require referral to emergency services for an expert evaluation of the extent of the contamination of the site and appropriate decontamination measures. Exposures in the laboratory or nuclear medicine suites require referral to the radiation safety officer in the building for a similar evaluation.

When considering a local incident involving nuclear material, first responders will likely include a hazardous materials team (HAZMAT), local police and fire departments. Hospitals should involve their radiation safety officer (RSO) and public officials will involve a state agency such as the State Department of Environmental Protection. As part of its primary

mission for the US Department of Energy, REAC/TS offers consultation with anyone on a 24/7 basis on questions regarding radiation exposure. Its emergency phone number is 865-576-1005 (ask for REAC/TS). For large incidents, other federal agencies will be involved led by the Federal Emergency Management Agency. Additional radiation expertise can be provided via the Department of Energy, and if applicable the Federal Bureau of Investigation will protect against further threats.

In a mass-casualty event, established prehospital plans should be followed to provide the best management for the large numbers of variously injured given that the radiation exposure may also be accompanied by an explosion of potentially catastrophic size. First responders must use universal precautions and should assume that all victims are contaminated; most events will only require C-or D-level protection ([Chap. 131](#)). Field triage protocols tailored to the kind of event in question will designate patients as minor, delayed, immediate, or deceased and should not be altered because of radiation exposure.

Preliminary decontamination, including removal of clothing and washing the victim, should be performed before transportation to a medical facility taking care not to contaminate prehospital providers or equipment. Uninjured patients who are contaminated should be relocated upwind of the incident site for further care.

Initial Emergency Department Management

It is not considered a medical emergency to have been irradiated or contaminated; even highly irradiated patients take days to die, which is why standard protocols regarding trauma and other medical complaints continue to be followed, even in mass casualty events. In the event of a radiation incident, there will likely be little warning of these patients arriving and information will be incomplete. Ideally, the emergency department is divided into clean and dirty areas where the dirty area is covered by plastic or butcher's paper. Staff should don surgical scrubs, gowns, surgical caps, masks, and booties, as well as a face shield. Two sets of gloves should be worn with the inner set taped to the gown. Tape should also close the back of the gown and trousers to the booties. Dosimeters should be worn at the neck for easy access by the RSO and staff should be reminded that medical personnel have never received a medically significant acute radiation dose when caring for an exposed patient.

Due to the complex nature of radiation and contamination, it will be necessary to call upon the various consultation services, who will likely be a part of the hospital medical response team, that can lend their expertise. These services include burn specialists, dermatology, nuclear medicine, radiation oncology, hematology, toxicology, and the RSO.

When patients arrive to the emergency department (ED) it is critical to follow an algorithm that takes into account issues of irradiation or contamination and includes data collection specific to biodosimetry. One such algorithm is the REAC/TS patient treatment algorithm at <http://orise.orau.gov/files/reacts/radiation-patient-treatment-algorithm.pdf>. Important patient history includes their location during the incident, duration of the exposure, time interval between exposure and clinical evaluation, occupation of the victim, and also whether the patient has had a recent nuclear medicine procedure. Physical examination, in addition to airway, breathing, and circulation should focus on vital signs, skin (erythema, blisters, desquamation), gastrointestinal symptoms (abdominal pain and cramping), neurologic findings (ataxia, headache, motor or sensory deficits), and hematologic signs (ecchymoses or petechiae). Vomiting very early after exposure is considered a sign of the central nervous system (CNS) subsyndrome and is a poor prognostic indicator.

Initial laboratory testing should include baseline complete blood count (CBC) with differential (including an extra sample in a heparinized tube for cytogenetics), serum amylase (increased from specific salivary gland inflammation and degeneration), urinalysis, baseline radiological assessment of urine, and begin a 24-hour urine collection. Other laboratory tests, if possible, may include blood FLT-3 ligand levels, blood citrulline, interleukin-6, quantitative granulocyte colony-stimulating factor (G-CSF), and C-reactive protein. Nasal swabs, emesis, and stool may be collected for radiological monitoring. For patients with persistent vomiting erythema or fever, obtain a repeat CBC with differential every 4 to 6 hours. If a patient should require surgery, the Armed Forces Radiobiology Research Institute recommends that surgery proceed immediately because of the delayed and impaired wound healing associated expected decreases in leukocytes and platelets.

Decontamination

Once a patient is medically stable decontamination may proceed. Patients who were not decontaminated prehospitally but who are grossly contaminated should be fairly easily detected as such by a quick look with an appropriate instrument. As a first step all clothing should be removed gently by cutting and not tearing as is typically done for trauma patients. Rolling supine patients allows contaminated clothes to be carefully gathered and bagged and marked. Bagged clothes and other contaminated articles should be removed from the ED to a site designated by the RSO so as not to present another source of radiation. A portable dosimeter should assist in external decontamination. After clothing removal, re-monitor the patient for contamination paying attention to exposed areas such as hair. Contaminated hair should be washed with soap and water before washing the body to avoid trickledown contamination. For patients with contaminated wounds, decontamination should prioritize the wound first, then body orifices around the face, then intact skin. Always wipe gently away from the wound. Irrigate gently to reduce splashing. Care must be taken not to abrade skin by too vigorous scrubbing or shaving of

hair. Contaminated nares can be cleared often by having the patient blow his or her nose. Ideally, all irrigating fluids are collected for analysis but this will be limited by resources and event details. There should be no eating, drinking, or smoking at the scene of decontamination.

For patients with smaller exposures to radionuclides, such as laboratory workers, decontamination is often the only management technique required to limit injury. Portable dosimeters will identify contaminated areas, which may be sealed off to limit spread of exposure, especially if the radionuclide is in gaseous form. As with larger exposures, contaminated clothing must be removed and collected. Contaminated skin must be washed with lukewarm soap and water, repeatedly if needed.

In evaluating an area in which a spill of radioactive material has occurred, a judgment must be made regarding the severity of the incident so that appropriate steps are taken. If a major incident has occurred involving large amounts of radioactive material, a large contaminated area, airborne radioactivity, or spread of radiation outside an authorized area, evacuation, notification of the radiation safety officer in an institutional setting, and calling local or regional emergency response personnel are recommended. Minor incidents involve small amounts of radioactive material where the individual knows how to clean the site, has appropriate decontamination material on hand, and can clean the area in a reasonably short time. Several different decontaminating agents are commercially available from general stores and many scientific suppliers. These agents come in the form of concentrated detergents or foaming sprays where a small spill is quickly wiped clean and disposed of in an appropriate container.

Medical Decision Making

Exposure to radiation can lead to a complex spectrum of organ damage that can be difficult and confusing for physicians when creating a treatment plan. Establishment of guidance in the form of a response category (RC) helps clarify a medical plan and disposition (Table 134–4). Following exposure to radiation, quantitative and semiquantitative criteria can be used to describe different degrees of injury to affected organ systems. Combining descriptions of the patient’s severity among categories of hematopoietic, cutaneous, gastrointestinal, and neurovascular subsyndromes allows assignment of a grade of injury. For example, a patient with a third-degree cutaneous injury but only first- or second-degree injuries to the other systems would be given an RC grade of 3, giving the cutaneous injury the greatest weighting since its severity would then carry the worst prognosis. This RC grade then suggests a certain level of care whether ambulatory versus inpatient versus intensive care unit, as well as use of specific treatments such as blood transfusion versus colony-stimulating factors (CSFs) versus bone marrow transplantation. (For specific suggestions, refer to the interactive version of this assessment tool at the Radiation Emergency Medical Management Web site at www.remm.nlm.gov.) It is essential to remember that following a mass-casualty event, response assets from facilities to medications to personnel may be diminished significantly and that recommendations using this system may be modified in accordance with other recommendations concerning crisis standards of care.^{6,7}

TABLE 134–4. Grading System for Organ System Dysfunction and Response Category for Disposition

Symptom	Degree 1	Degree 2	Degree 3	Degree 4
Neurovascular System				
Anorexia	Able to eat	Decreased	Minimal	Parenteral
Nausea	Mild	Moderate	Severe	Excruciating
Vomiting	1/day	2–5/day	6–10/day	> 10/day
Fatigue	Able to work	Impaired	Assisted ADL	No ADL
Fever	(< 38°C)	(38°–40°C)	(> 40°C) < 24 hours	(> 40°C) > 24 hours
Headache	Minimal	Moderate	Severe	Excruciating
Hypotension (blood pressure, mm Hg)	> 100/70	< 100/70	< 90/60	< 80 systolic
Cognitive deficits	Minor	Moderate	Major	Complete
Neurological deficits	Barely detectable	Easily detectable	Prominent	Life threatening
Hematopoietic System (all counts $\times 10^9/L$)				
Lymphocytes	1.5–3.5	0.5–1.5	0.25–1	0.1–0.25
Granulocytes	4–9	< 1 ^a	< 0.5 ^a	0–0.5
Platelets	150–350	50–100	0–50	Very low ^b
Gastrointestinal System				
Diarrhea				
Frequency (/day)	2–3	4–6	7–9	≥ 10
Consistency	Bulky	Loose	Loose	Watery
Bleeding	Occult	Intermittent	Persistent	Large, persistent
Abdominal cramps/pain	Minimal	Moderate	Severe	Excruciating
Cutaneous System				
Erythema	Minimal	< 10% BSA	10%–40% BSA	> 40% BSA
Edema	Asymptomatic	Symptomatic	Secondary dysfunction	Total dysfunction
Blistering	Rare, sterile	Rare, bloody	Bullae, sterile	Bullae, bloody
Desquamation	Absent	Patchy, dry	Patchy, moist	Confluent, moist
Ulceration/necrosis	Epidermal	Dermal	Subcutaneous	Muscle/bone
Hair loss	Absent	Partial	Partial	Complete
Response Category				
	1, Some 2	2	3	4
	Ambulatory		Hospitalization	
General supportive care, usually no specific therapy		Supportive care, blood products	Blood products, CSFs ICU	Blood products, CSFs, SCT Specialized hospitals ^c

^aAn absolute rise in cell counts begins between days 5 and 10, which lasts about 8 to 12 days. Afterward, cell counts decline slowly reaching a nadir around day 20. ^bCell counts decline faster reaching lower nadir for more severe exposures at about days 22, 16, and 10 for grades 2 to 4. ^c"Specialized hospitals" refers to those with experience in all areas of intensive care medicine, particularly allogeneic SCT.

ADL = activities of daily living; BSA = body surface area; ICU = intensive care unit; CSFs = colony-stimulating factors; SCT = stem cell transplantation.

Data from References 6 and 7.

Medical Management

Supportive care quality will determine the extent of the morbidity and mortality. The majority of patients with ARS who succumb usually do so from fluid loss, infection, or bleeding. Irradiated patients may require treatment for nausea and vomiting, diarrhea, pain, and fluid and electrolyte losses. Vomiting is thought to occur as a result of serotonin release from damaged gut tissue. The 5-HT₃ antagonists, such as ondansetron (0.15 mg/kg intravenous {IV}) or granisetron (10 µg/kg IV), are the most effective medications to control vomiting. Prolonged antiemetic treatment is usually not necessary since emesis often resolves within 72 hours. Loperamide, anticholinergics, or aluminum hydroxide can be utilized to treat diarrhea. Mild pain may be managed with acetaminophen, but aspirin and nonsteroidal drugs are not recommended as they may exacerbate gastric bleeding. An opioid is recommended for the management of more severe pain.

Probiotics is the introduction of selective nonpathogenic strains of *Lactobacillus* and *Bifidobacteria* into the gastrointestinal tract to suppress the number of pathogens. Experimentally, this technique increased survival in canine and

rodent models. Probiotics was used to help care for three men exposed at the incident at Chernobyl, whose survival time was prolonged, although it was not statistically significant when compared, respectively to case controls.^{4,34}

Intravenous access should be established and maintained with care as they are prone to infection. If the patient is expected to become neutropenic, then consider establishing central venous access or placement of a peripherally inserted central catheter. Fluid replacement may begin with crystalloid solution with the goal of replacing gastrointestinal losses. The infusion rate will be modified by recorded inputs and outputs and assessment of surface area burns.

Prevention of infection includes attention to several aspects of care. Maintain the patient in a clean environment and institute reverse isolation for patients with at least moderate exposure or when neutrophil counts decline below 1000/ μ L. Prophylactic antibiotics and antifungals should be considered for neutropenic patients, as well as acyclovir or a congener for herpes simplex virus positive patients. If neutropenic patients become febrile, follow Infectious Disease Society of America (IDSA) guidelines for antibiotic choices. Consider broad-spectrum prophylactic antibiotic coverage, including anaerobic coverage for patients with burns.^{6,8}

Cutaneous injuries are cared for depending on the nature, location, and extent of the wounds. Care ranges from use of soothing agents or topical steroids, to drying agents and debridement, to skin grafting. Use of pentoxifylline may assist with healing. Surgical consultation or referral to a burn center may be offered.

Cytokine therapy (colony stimulating factors {CSFs}) use in radiation-exposed patients is based on demonstrated enhancement of neutrophil recovery in patients with cancer, a perceived benefit in a small number of radiation-incident victims, and several prospective trials using different animal models involving radiation exposure. These last studies demonstrated not only neutrophil recovery but also a survival advantage. The best outcomes were demonstrated when started less than 24 hours postradiation suggesting CSFs should be started as soon as possible for patients exposed to a survivable dose of radiation who are at risk for hematopoietic syndrome, that is, more than 3 Gy. Additionally, patients at extremes of age, that is, those younger than 12 years and the elderly, are considered to be more susceptible to radiation and may benefit from CSFs when exposed to lower threshold doses.⁸

Use of blood products is required for patients with significant blood loss or for those experiencing radiation-induced aplasia. This latter complication usually begins several weeks following exposure allowing for time to identify potential donors. Use of leukoreduced and (ironically) irradiated blood products should be the rule to prevent transfusion-associated graft-versus-host disease. This hyperacute complication may be further complicated by its similarity to radiation-induced organ injury, including fever, pancytopenia, rash or desquamation, diarrhea, and hyperbilirubinemia.

Stem cell transplantation (SCT) may be used to treat patients with severe bone marrow injury, but appropriate use of this therapy is complicated by a number of issues. Currently, it is believed that with aggressive supportive care and early use of CSFs, patients merely suffering from hematopoietic syndrome may survive a radiation dose of 7 to 8 Gy, but doses greater than 10 Gy are likely to be fatal, providing a narrow window of opportunity, even if an appropriate match could be found. Additionally, there are complicating factors including the manner in which exposed dose was estimated, and other potentially significant concurrent organ injuries such as burns and acute respiratory distress syndrome, which historically have accounted for 70% of radiation deaths.⁶ When caring for the severely exposed patient, consultation with a hematologist is likely the best course when considering SCT.

Management of Internal Contamination

Internal contamination is assessed differently from external doses. First, internal doses are not measured but calculated. Calculations are performed by a health physicist on samples such as nasal swabs, urine, or stool to estimate how much activity entered the body. Doses are termed committed doses defined as the doses received that last more than 50 years due to the internal deposit of the radionuclide. That is, the radionuclide dose is protracted and remains until it decays or is eliminated via normal kinetic processes. These doses are compared with the annual limits on intake (ALIs) provided by the EPA as a benchmark for medical decision making. Interpretation of committed doses from contaminated wounds requires special conversion factors provided by the NCRP.

Management of internal contamination is isotope dependent. There are more than 8000 isotopes, thus making identification of the particular isotope in question critical. Although both radioactive decay and biologic elimination contribute to an even shorter effective half-life, medical treatment is directed at one of several categories including reduction of gastrointestinal absorption, blocking uptake (as with potassium iodide), isotopic dilution (water for tritium), chemical manipulation (sodium bicarbonate for uranium), excision of shrapnel, and chelation. Both NCRP reports 65 and 161 provide comprehensive information regarding decorporation of radionuclides; however, for the few isotopes of particular concern for industry, the military, and academic and medical centers, potassium iodide and pentetic acid (DTPA) would be the most commonly applicable chelators (Antidotes in Depth: A43 and A44).

PROGNOSIS

The prognosis of those exposed to radiation varies with the amount of the exposure, the type of medical care received, and

the number of casualties in a given exposure scenario. Survival is inversely proportional to the radiation dose absorbed, and even the relatively radioresistant cell types can be killed by high amounts of radiation. Historically, the mean lethal dose required to kill 50% of humans at 60 days ($LD_{50/60}$) was about 3.5 Gy without supportive care. The addition of antibiotics and blood products support increases that mean to 6 to 7 Gy. This dose may be even higher for those treated early with CSFs in a specialized hospital. Coexisting traumatic injuries or burns will decrease the $LD_{50/60}$. An acute dose of 20 Gy or more is considered supralethal. Historically, those who were exposed to greater than 10 Gy died despite care including one worker at Tokaimura who was exposed to 17 Gy who died 3 months postexposure, and 20 of 21 workers who were exposed to radiation in the 6-to 16-Gy range at Chernobyl. Some authors suggest that those exposed to 10 Gy or greater be given supportive and comfort care only because their survival is considered to be unlikely.^{5,36}

CONSIDERATION OF THE DECEASED

Contaminated bodies should be placed in a temporary morgue that is refrigerated. Use of the hospital morgue may lead to contamination there. These bodies should not be cremated since this will only redistribute the nuclear material, which is not destroyed by fire. Respect should be paid to the religious beliefs of family members of the deceased for whom cremation may be the custom.

PREGNANCY AND RADIATION

When exposure to radiation via medical examination is possible, pregnant women and physicians have exhibited great concern over possible injury to the fetus. In general, radiation effects to an embryo or fetus are dependent on its stage of development and the dose received. The medical decision to perform imaging or a diagnostic procedure that may expose any patient to radiation is always based on a risk–benefit analysis with a given patient’s situation.

In the normal course of events, uncertainty exists regarding the normal viability of the fertilized ovum where the baseline risks of birth defects and miscarriage are 3% and 15%, respectively, for women with normal genetic and reproductive history. Very early in a pregnancy before implantation the embryo is in an “all-or-none” period of development where the greatest risk from radiation is miscarriage, but not greater than baseline risk. Older than this, the fetus is next at greatest risk between 8 to 15 weeks where major neuronal migration takes place.

The NCRP considers risk to the fetus to be negligible compared with other risks of pregnancy when the dose to the fetus is less than 50 mGy (5 rad) which corresponds to 50 mSv from x-ray examination, compared with about 6 mSv effective dose from a CT examination of the pelvis. The risk of malformation is increased only at doses above 150 mSv. As mentioned earlier, special attention must be paid to pregnant or potentially pregnant patients when deciding if an examination or procedure involving radiation is considered. Effective doses from various examinations and procedures are known to range from 0.1 mSv from posteroanterior and lateral x-ray of the chest to 15 mSv from CT angiogram of the chest, to 40.7 mSv from cardiac stress test with ^{201}Tl . The vast majority of routine diagnostic imaging procedures imparts less than 5 mSv to the fetus, increasing baseline risk by about 0.17%, and so is considered to be of negligible risk, but consideration should always be given to the potential maternal benefit of the radiologic procedure and the potential risk to the fetus.

PEDIATRICS AND RADIATION

The use of CT scanning in children has markedly increased over the last 30 years. Estimates include data that, commensurate with the 20-fold increase in use of CT scans in the United States, the use of CT for pediatric patients has increased by about eight times. The reasons for this increase are many including greater availability, greater use as a primary diagnostic tool, and an increased perception that the risk of being wrong about a diagnosis is high.^{2,23} Other estimates calculate an increased risk of lifetime mortality in the range of 0.04% for a head CT for a young female patient (1 in 2500) compared with a normal cancer mortality risk of 20% (1 in 5). This excess relative risk was supported by a large retrospective study of a pediatric population that found increased incidence of certain leukemias and certain brain tumors attributed to CT scans over a 23-year period.²⁷

Although radiation is considered to be a weak carcinogen and radiographic studies should continue to be ordered in the best interest of the patient, it is likely that the number of scans performed could safely be diminished without compromising care. Reports on this topic commonly include problems with ordering unnecessary multiple CTs, follow-up CT scans, and CT scans that occur simply due to a lack of communication between patient, health care professional, and technician. These problems, compounded by inappropriate CT protocol for pediatric patients, suggest that the medical community could be more proactive in reducing the health risk of those in our charge.

SUMMARY

- Ionizing radiation injures humans through the disruption of cellular structure and function that can lead to cell death and or mutagenesis.
- Fortunately, large exposures of radiation to the general population are rare outside of the setting of an armed conflict and most contaminations that occur are small and easily controlled.
- Recognition of the exposure and thorough decontamination are the critical steps to minimizing the potential toxicity of an exposure.
- Prognosis is based on dose which can be estimated on a number of clinical and laboratory grounds.
- Although consequential, neither contamination nor incorporation should take precedence over the highest priorities of emergency care and urgent surgery.

A43 ANTIDOTES IN DEPTH

Potassium Iodide

Joseph G. Rella

INTRODUCTION

Potassium iodide is the antidote to radioactive iodine that may be released into the atmosphere following a nuclear incident. It is approved as a specific blocker of thyroid uptake of radioiodine to reduce the risk of thyroid cancer in susceptible populations. The indications for its use are complex and initiation and maintenance of therapy require great attention to the details of the circumstances of the exposure to limit harm that may result from either undertreatment or overtreatment.

HISTORY

Following the study of thyroid cancers in Pacific Islanders who were subjected to fallout from nuclear testing, scientists concluded in 1957 that potassium iodide (KI) could effectively protect the thyroid from radioactive iodine. The National Council on Radiation Protection and Measurements (NCRP) reported in 1977 that the sudden release of radionuclides, including radioiodine, could affect large numbers of people following a nuclear incident (Fig. A43–1). The following year the US Food and Drug Administration (FDA) requested the production and storage of KI for the purpose of blocking the effects of radioiodine on the thyroid gland when needed.

FIGURE A43–1. The decay pathway that describes how ^{131}I is derived from nuclear fuel (whether in a bomb or a reactor) and ultimately decays to stable xenon. s = seconds; m = months; d = days.

PHARMACOLOGY

Chemistry

Iodine is a chemical element, symbol “I,” atomic number 53. Its name derives from the Greek *iodes* meaning violet, owing to the violet color of elemental iodine vapor. Like other halogens, iodine occurs mainly as a diatomic molecule I_2 . Although it is considered a relatively rare element, it is the heaviest essential element used widely in biologic functions. Of 37 iodine isotopes, only ^{127}I is stable. The term iodide refers to the ion I^- , which forms inorganic compounds with iodine that is in the oxidation state -1 , such as potassium iodide.

Mechanism of Action

Neonates, children, and adolescents are particularly susceptible to the toxic effects of radioactive iodine. During the growth periods for these groups there is increasing growth of the thyroid gland, as well as an increase in thyroglobulin and iodothyronine stores. Thyroid tissue also accumulates a larger percentage of exogenously ingested iodide and more efficiently reuses iodine from degraded hormone. This increased activity during these growth periods explains the greater risk for developing thyroid cancer in children compared to adults following exposure to radioactive iodine. During pregnancy, the maternal thyroid gland is stimulated and takes up more iodine compared to other adults, thus increasing susceptibility in pregnant women to the toxic effects of radioiodine.

Exposure to radioactive iodine may occur via inhalation or via ingestion of contaminated food, as occurred following the Chernobyl incident. Radioiodine may be rapidly absorbed from either the digestive or respiratory tracts. Once incorporated into the thyroid gland, radioiodine exposes thyroid tissue to β and γ emissions, potentially leading to genetic alterations and cancer.³ This is the stochastic effect of radiation (Chap. 134).

Because the chemical properties of radioactive iodine are unchanged from stable iodine, prophylaxis with KI is effective via isotopic dilution. That is, KI competes with radioactive iodine for the active iodine transport system to reduce or dilute the concentration of radioiodine in the serum making the uptake of radioiodine much less likely, essentially blocking it.

Evacuation and Food Interdiction. KI is not a panacea for radiation exposure. Even if appropriately used during a release of ^{131}I , KI will not protect against direct radiation exposure or against other radioactive elements that may be included in fallout (ie, cesium and strontium). Depending on radiation levels, communities may be evacuated from areas surrounding a nuclear power plant experiencing a release of radioactive material. Evacuation is most effective if implemented before the passage of a radioactive plume, but this should be guided by dose estimates provided by public health authorities.

The FDA and World Health Organization (WHO) both recommend food interdiction and food control as the principal means to limit public exposure to contamination. Contaminated food that is subsequently canned may ultimately pose no risk to the population if it is stored for sufficient time to allow the radioactive iodine to decay completely. The WHO considers food control to be preferable to iodine prophylaxis and the removal of milk from the diet of some populations to be unfortunate but acceptable.^{5,16}

Pharmacokinetics

Dietary iodine is well absorbed from the small intestine under normal conditions. It distributes selectively into the thyroid gland, but also to a lesser extent into salivary glands, choroid plexus, and gastric mucosa. Iodine has a volume of distribution of 0.3 L/kg. During pregnancy and lactation, iodine distribution to mammary glands and ovaries increases.

Iodide that is not concentrated in the thyroid is excreted 80% in urine and 20% in feces, although additional losses via sweat can occur and can become an important route of loss in warmer climates. Urine iodine concentrations reflect plasma concentrations and have been used for years as a means to assess dietary iodine intake.

Pharmacodynamics

Iodine, or its ionic form iodide (I^-), is an essential nutrient present in humans in minute total body amounts of 15 to 25 mg. Iodine is required for the synthesis of the thyroid hormones L-triiodothyronine (T_3) and L-thyroxine (T_4), which in turn regulate metabolic processes and determine early growth of most organs, especially the brain. Iodide is actively transported with sodium into thyroid follicular cells, where it is concentrated 20 to 40 fold compared with its serum concentration. It is then transported into the follicular lumen where it iodinates thyroglobulin to form T_3 and T_4 (Chap. 56). Thyroid hormones are metabolized in hepatic and other peripheral (meaning extrathyroid) tissues by sequential deiodination.

ROLE IN RADIOACTIVE IODINE EXPOSURE

Studies have shown over the last 50 years that radioactive iodine uptake can be effectively blocked by KI supplementation.² In nuclear radiology, administration of iodine containing contrast media can deliver up to 45 times the recommended daily intake of free iodine and delay the uptake of therapeutic ^{131}I for several weeks.^{7,15} Following the incident at Chernobyl, the Polish government distributed nearly 18 million doses of KI to the people in its most affected provinces (in addition to food interdiction), while none was distributed to affected areas of Ukraine and Belarus. Studies of these differently treated populations who were exposed to the radioactive plume clearly demonstrated not only a dose-response relationship between radiation dose and the relative risk of thyroid cancer, but also a threefold reduction of this risk via KI supplementation.^{3,9} Although some controversy exists regarding increased numbers of detected thyroid cancers possibly due to improved screening, other studies bear out the true increase in these tumors, and also distinguished by genetic analysis radiation-induced cancers from sporadic papillary cancers.^{1,10}

After the Fukushima incident, the Japanese government gave orders to distribute KI at evacuation sites, but this did not occur. Data on the aftermath of this event are still forthcoming. Interestingly, a shortage in the United States of commercially available KI existed at the same time.¹¹ Chernobyl remains the largest experience of KI distribution following a release of radioactive material from a nuclear incident from which data and recommendations are derived.

ADVERSE EFFECTS AND SAFETY ISSUES

Thyroidal Effects

Extensive experience with treating goiter and the use of nutritional supplements in the form of iodized salt has shown that both hyper- and hypothyroidism may result from supplementation with KI.¹³ Specifically, treatment with KI is linked to

occasional hyperthyroidism, and iodized salt programs have been associated with subsequent hypothyroidism and thyroid autoimmunity. Both the prevalence of goiter and subclinical hypothyroidism can increase when iodine intake is chronically high. The Wolff-Chaikoff effect, where high concentrations of iodine inhibit the synthesis of thyroid hormones, may be devastating to fetal neurologic development in pregnant women treated with KI, which is why both the FDA and WHO advise against repeat dosing of KI for pregnant women if possible.^{5,16}

A large study in Poland following the Chernobyl incident investigated the risks and benefits of KI prophylaxis. Of the thousands of men, women, and children who were studied, the vast majority of whom received a single dose of KI, no statistical differences were found between treated and untreated groups when thyroid stimulating hormone (TSH) concentrations were measured among all populations. Additionally, among adults with thyroid disease, no cases of thyrotoxicosis or exacerbation of preexisting thyroid conditions were found. Although pregnant women were not mentioned per se, children born in 1986 and examined in the second and third years of life showed no difference in thyroid status compared with those born after radioiodine was gone from the environment. In newborns, 12 of 3214 treated on the second day of life showed transient decreases in serum free T₄ but had no clinical sequelae.⁸ Another systematic review of studies reporting adverse effects of iodine used for thyroid blocking, which also did not mention pregnant women, concluded that KI supplementation seemed not to induce severe adverse effects, but also that scientifically sound studies of this subject are scarce and provide only weak evidence.¹³

Extrathyroidal Effects

Many extrathyroidal effects of KI are described. Sialadenitis, or iodide mumps, is an inflammation of the salivary glands and appears to be unpredictable. Iododerma is a rare and reversible acneiform eruption related to iodine ingestion that may result from nonspecific immune stimulation.¹¹ Other reactions reported in association with KI use include gastrointestinal disturbances, fever, and shortness of breath.

Although some reports use imprecise definitions when attributing adverse reactions to iodine or iodide-containing medications, “allergy” refers to a specific immune response to target proteins via an immunoglobulin E (IgE) triggered release of cell mediators, such as histamine. There are no studies that demonstrate IgE antibodies to small molecules such as iodine or iodide.

“Allergy” to radiocontrast media is actually an anaphylactoid response to the high osmolality of these xenobiotics. Anaphylactoid responses manifest by release of similar mediators to anaphylactic response but via non-IgE-mediated pathways. An anaphylactoid response to iodine-containing medications or iodinated contrast materials may be predicted in patients with asthma, allergic rhinitis, and food allergies to chocolate, eggs, and milk. While seafood may contain iodine, allergy to fish or shellfish is due to specific marine proteins and not sensitivity to iodine. Patients manifesting allergic contact dermatitis resulting from iodine containing cleaning preparations such as povidone-iodine do not react to patch testing with KI. Therefore, when physicians consider the safety of KI dosing in the event of radioactive iodine exposure, reactions to radiocontrast media, seafood, and povidone-iodine should not be interpreted as an allergy to KI. Physicians must also consider that there are inactive ingredients or diluents of the KI formulation.

PREGNANCY AND LACTATION

Potassium iodide is listed in pregnancy category D and readily crosses the placenta and distributes into milk. Both the FDA and WHO support the use of KI for pregnant women when instructed to do so by public health authorities.^{5,16}

DOSING AND ADMINISTRATION

After reviewing data from Chernobyl regarding estimated doses and cancer risks in exposed children, the FDA provided recommendations for KI supplementation for various populations, depending on their relative risks (Table A43–1).^{5,16}

TABLE A43–1. Threshold Radiation Exposure Doses and Recommended Potassium Iodide KI Doses for Different Risk Groups

	Predicted Thyroid Exposure		KI Dose (mg)	Number of 130 mg Tablets	Milliliters of Oral Solution, 65 mg/mL
	Gy	rad			
Adults > 40 years of age	≥ 5	≥ 500	130	1	2
Adults 18–40 years of age	≥ 0.1	≥ 10	130	1	2
Pregnant or lactating women	≥ 0.05	≥ 5	130	1	2
Children and adolescents 3–18 years of age ^a	≥ 0.05	≥ 5	65	1/2 ^a	1
Children 1 month–3 years of age	≥ 0.05	≥ 5	32	Use KI oral solution ^b	0.5
Children birth to 1 month of age	≥ 0.05	≥ 5	16	Use KI oral solution ^b	0.25

^aAdolescents approaching adult size (70 kg) should receive a full dose of 130 mg. ^bFor smaller, more precise dosing, a KI oral solution is available with a dropper marked for 1, 0.5, and 0.25 mL dosing.

Source: FDA website.¹

Adults older than 40 years of age face a near-zero risk of developing thyroid cancer from exposure to radioactive iodine. For this group, the complications from iodide supplementation, such as goiter or Graves disease, would likely outweigh any benefit in the setting of relatively mild exposure. However, if public health experts determine that exposure dose may be 5 Gy (500 rad) or greater, which is only likely to occur for those living within a 10 mile radius of a nuclear power plant release, KI is recommended.

Adults 18 to 40 years of age are at risk of developing thyroid cancer that is approximately equal to the risks of side effects of a single dose of iodide supplementation, although it should be understood that both risks are very small. The decision to treat should be based upon the threshold criteria used as well as the risks of iodine supplementation, such as iodine reactions, or a history of past thyroid disease.

Lactating mothers should take KI when instructed to do so by public health authorities. KI is secreted in breast milk and will offer some protection to a neonate, but the risks of treatment are much higher in these patients requiring greater attention to monitoring, as discussed below.

Pregnant women have increased thyroid uptake of iodine, especially in the first trimester, compared with other adults. The developing fetus has increased iodine uptake during the second and third trimesters. Because iodine crosses the placenta, the fetus may potentially be exposed to radioactive iodine, thus supplementation with KI is only recommended at appropriate exposure thresholds.

Children 1 month to 18 years of age are at high risk of thyroid cancer from exposure to radioactive iodine and are at low risk of side effects from supplementation with KI. Therefore, supplementation for children in this age group should begin promptly following official notification of a potential radioactive iodine release.

Neonates are at significantly increased risk from exposure to radioactive iodine because of a marked increase in uptake of iodine resulting from neonatal body cooling in the immediate postdelivery period. At the same time, neonates are susceptible to functional blocking by overloading with stable iodine. Therefore, when supplementation is indicated, KI should promptly be given to neonates with critical attention to dosing. The WHO recommends the KI solution be available for maternity wards in the precise dosing for newborns. Since the most critical time period for thyroid blockage is within the first postpartum week, dosing neonates who are older than one week may be performed at home via dividing, crushing, or suspending tablets in milk, formula, or water.

Timing of Administration

For full blocking effect, KI should be administered shortly before exposure or as soon as possible afterward. Some models describe the blockade of only 50% of iodine uptake when there is a delay of several hours following an exposure.⁶ Depending on the duration and type of risk, administration of KI months after an exposure may also partially reduce thyroid cancer risk.^{6,17}

Daily Versus Single Dosing

The protective effect of potassium iodide lasts for about 24 hours, so it should be dosed daily for those groups in whom an ongoing risk is perceived. Depending on the dosing estimates for exposure, this group is primarily children aged 1 month to 18 years. Groups in whom a single dose is recommended include pregnant women and neonates, where there is a significant risk of causing harm to the fetus via impaired cognitive development. For lactating women, stable iodine will be delivered to the nursing newborn and may cause functional blocking of iodine uptake by an overload of iodine. Therefore, the FDA recommends that lactating mothers not receive repeated doses except during continuing, severe contamination, which would generally be defined by health officials.

As mentioned previously, Chernobyl is the most significant massive release of radioiodine in history and nearly all of our experience and recommendations in this type of setting derive from this one event. Although distribution of radioiodine was uneven in Poland, the air concentration of radioiodine had decreased fourfold one week after the first explosion. Therefore, KI prophylaxis was not repeated. It is perhaps based on this experience that it is generally thought that no more than one or two doses of KI would be needed following release of a single radioactive plume, during which other protective measures such as food interdiction or sheltering measures are implemented. While the possibility exists that many repeated releases of radioactive gas might require prolonged prophylaxis, repeat dosing for days to weeks may not be necessary.

Monitoring

Normal thyroid function is critical for proper brain development in a fetus. Just as a fetus and newborn is susceptible to radioiodine uptake, they are also at risk for development of hypothyroidism from repeat dosing of KI. All neonates who are treated with KI in the first weeks of life should be monitored for changes in thyroid stimulating hormone (TSH) and free T₄. Likewise when a lactating mother requires repeat doses of KI, the nursing infant should also be monitored for the development of hypothyroidism.

FORMULATION AND ACQUISITION

Several manufacturers formulate potassium iodide and market them as nonprescription, FDA approved products with a shelf life of 7 years. Longevity studies over many years have demonstrated the active ingredients of KI to be very stable. Recognizing that many state and local governments maintain stockpiles of KI for use in the event of a radiation emergency (KI is a part of the US Strategic National Stockpile (SNS), which consists of a large quantities of medications and supplies ready for use in a public health emergency), the FDA has developed guidelines for shelf life extension that manufacturers may use to extend the shelf lives of their products in increments of 2 years.⁴ Tablets are available in both 130 mg and 65 mg doses, as well as an oral solution in a concentration of 65 mg/mL. Iodide containing products not considered useful in radioiodine protection include iodized salt, seaweed, and tincture of iodine.

SUMMARY

- KI is a safe and effective means of blocking the uptake of ¹³¹I following a nuclear catastrophe.
- Firm reliance on the evaluation of health officials of the risk of exposure is vital since the overall likelihood of exposure to the critical radiation threshold is very low, except for those living within 10 miles of a nuclear reactor.
- Exposed persons should strictly adhere to dosing guidelines to minimize the potential risks of KI dosing, especially in pregnant women and newborn children.
- “Iodine allergy” is not a contraindication to KI administration in the setting of a confirmed release of radioactive iodine.
- Food interdiction and environmental evacuation or avoidance of the radioactive plume are preferable to KI prophylaxis in the event of a potential exposure and may obviate the need for KI completely.

A44 ANTIDOTES IN DEPTH

Pentetic Acid or Pentetate (Zinc or Calcium) Trisodium (DTPA)

Joseph G. Rella

INTRODUCTION

Pentetate zinc trisodium and pentetate calcium trisodium (zinc or calcium diethylenetriaminepentaacetate; Zn-DTPA and Ca-DTPA, respectively) are chelators for certain heavy metals and radionuclides. They are approved for the treatment of internal contamination with plutonium, americium, and curium that may occur following unintentional exposure to these metals or following exposure resulting from a radiation dispersal device or “dirty bomb.”

HISTORY

First synthesized in 1954, these chelators were used investigationally to enhance elimination of transuranic elements ([Chap. 12](#)).³ DTPA has been used for the extraction of metals from soil and as a treatment for iron overload and lead toxicity.^{2,8,21} DTPA and its derivatives have also been used to help with imaging and diagnostics and more recently in chemotherapeutics. Over the last decades, hundreds of human exposures to radionuclides as well as numerous animal studies helped to define the best practices for the use of these chelators, culminating in their approval by the US Food and Drug Administration (FDA) in 2004.

PHARMACOLOGY

Chemistry

Pentetic acid is a synthetic polyaminopolycarboxylic acid with a molecular weight of 393 Da; the calcium trisodium salt weighs 497 Da, and the zinc trisodium salt weighs 522 Da. It is slightly water soluble and bonds stoichiometrically with a central metal ion through the formal donation of one or more of its electrons.

Related Xenobiotics

Several xenobiotics are used in clinical practice to chelate metals. Among these are deferoxamine, dimercaptol (British anti-Lewisite), dimercapto-propane sulfonate, edetate calcium disodium (ethylenediaminetetraacetic acid), penicillamine, Prussian blue, succimer (dimercaptosuccinic acid), and trientine hydrochloride. However, none of these are effective chelators for transuranic (elements with atomic numbers > 92) metals.

DTPA is used to convey gadolinium contrast in magnetic resonance imaging and technetium in nuclear medicine imaging. Other xenobiotics have modified the DTPA molecule in conjunction with a monoclonal antibody directed toward specific antigens found on neoplasms, allowing an attached isotope, such as ¹¹¹In, to deliver site directed radiation treatment. These related xenobiotics include tiuxetan, pendetide, and pentetreotide.¹⁷

Mechanism of Action

The conjugate base of pentetic acid has a high affinity for metal cations. Pentetic acid wraps itself around the metal forming up to eight bonds, exchanging its calcium or zinc ions for a metal with greater binding capacity ([Fig. A44–1](#)). Remaining water soluble, the chelated complex is then excreted by glomerular filtration into the urine. DTPA has specific stability constants for the various elements that it chelates, which presumably explains the different binding efficacies of the calcium and zinc salts.

FIGURE A44-1. Trisodium zinc diethylenetriaminepentaacetate, where a transuranic element (Am, Pu, Cm) is substituted for Zn forming a stable chelate.

Pharmacokinetics

DTPA is rapidly absorbed via intramuscular, intraperitoneal, and intravenous routes, but animal studies indicate that DTPA is poorly (< 5%) absorbed by the gastrointestinal tract. Absorption via the lungs is about 20% to 30%. Its volume of distribution is small (0.14 L/kg in humans) and it is distributed throughout the extracellular space. It does not penetrate erythrocytes or other cells such as bone. The plasma half-life is 20 to 60 minutes, although a small fraction is bound to plasma proteins with a half-life of more than 20 hours. DTPA undergoes minimal, if any, metabolism. Only a minimal release of acetate has been demonstrated, and splitting of ethylene groups has not been detected. Elimination is via glomerular filtration, with more than 95% excreted within 12 hours, and 99% by 24 hours. While there are no specific data regarding dosing or clearance changes when chelating patients with kidney disease, individuals with kidney disease who receive ^{99m}Tc -DTPA or Gd-DTPA for imaging purposes demonstrate an increased elimination rate of these chelates with hemodialysis. This suggests that hemodialysis might augment transuranic chelate elimination in contaminated patients with kidney disease.^{12,22} Fecal excretion is less than 3%.

Pharmacodynamics

DTPA increases the urinary elimination rate of certain chelated metals. Animal data show that when treatment is begun within an hour of internal contamination, Ca-DTPA resulted in 10 fold greater rate of urinary elimination of plutonium as compared with Zn-DTPA. The greatest chelating capacity occurred immediately and for the first 24 hours following contamination while the metal was still circulating and available for chelation. Following the initial dose of Ca-DTPA, similar rates of elimination of radionuclide resulted from subsequent treatment with either Ca-DTPA or Zn-DTPA, although continued treatment with Ca-DTPA was associated with much greater toxicity, as described in adverse effects below. Animal studies showed that inhalational Ca-DTPA followed by a month-long regimen of Zn-DTPA reduced lung deposits of aerosolized plutonium to 2% of that compared with untreated animals.¹⁸

ROLE IN RADIONUCLIDE CONTAMINATION

DTPA is indicated and FDA approved for suspected contamination via inhalation, dermal, or wound exposure from plutonium, americium, and curium, with the goal of mitigating radionuclide incorporation and local tissue irradiation. Inhaled metals, such as might be experienced following an explosion, may be treated with nebulized DTPA. Depending on the chemistry of the metal (eg, uranium concentrates in renal tissue), this irradiation could possibly lead to development of a malignancy later in life. Chelation is indicated to increase elimination of the radionuclide and decrease cancer risk. This latter has only been demonstrated in animals. Increased urinary excretion of transuranic elements is a clinically meaningful endpoint for efficacy of DTPA. Administration of these chelators is not recommended following ingestion of americium, curium, or plutonium, because they will increase gastrointestinal absorption.

A report published by the Radiation Emergency Assistance Center/Training Site (REAC/TS) reviewed data from 685 transuranic element exposures, most of which were plutonium, curium, and americium. Most of these exposures (63.5%) were by inhalation, typically a breach of a confined area where workers access the radioactive material via arm-length gloves reaching into a protective box. Ages of the exposed ranged from 10 to 64 years of age. From the 18 patients with the most complete urine bioassay data, the average increase in urine elimination of radionuclide was 39 times the baseline rate after the first dose of DTPA.¹⁸ By 24 hours, postexposure soluble plutonium and americium are deposited in bone, theoretically rendering DTPA ineffective (in the absence of bone remodeling).⁷ Historic data concerning contaminated workers at nuclear materials production facilities, which included those who received both prolonged and delayed treatments, demonstrated greatly increased urinary excretion of radioactive material.^{1,9-11,19,20}

Other more limited data suggest that DTPA may also be effective in increasing urinary elimination following exposure to californium and berkelium, and some experts recommend DTPA for chelation of these elements. Animal data suggest the potential utility for chelating cobalt, einsteinium, lanthanum, nickel, promethium, scandium, strontium, yttrium, and yttrium. Pentetic acid salts are not effective in removing antimony, beryllium, bismuth, gallium, lead, mercury, neptunium, niobium, platinum, thorium, or uranium.

DTPA is neither recommended nor approved for treating patients contaminated with uranium or neptunium for several

reasons. DTPA mobilizes uranium from tissue stores but does not increase urinary elimination.^{5,14} Chelating incorporated neptunium is problematic because it forms very stable complexes with transferrin, making it very difficult to decorporate.^{6,13}

ADVERSE EFFECTS AND SAFETY ISSUES

A review of the clinical data by REAC/TS reported three deaths in patients with severe hemochromatosis who were treated with up to 4 g of Ca-DTPA per day. Three other patients experienced severe symptoms with similar dosing, including obtundation and lethargy, oral mucosal ulceration, stomatitis, dermatitis, and loss of lower extremity sensation. These reactions resolved upon cessation of Ca-DTPA administration. Injury was attributed to zinc depletion-induced impaired DNA synthesis in organs with rapid cell turnover.¹⁸ Caution is advised when treating individuals with severe hemochromatosis.

No serious toxicity has been reported among humans after more than 4500 Ca-DTPA administrations at recommended doses.³ Reported adverse reactions include nausea, vomiting, diarrhea, chills, fever, pruritus, and muscle cramps. Transient anosmia was observed in one individual after repeated treatments with Ca-DTPA, also possibly related to zinc depletion, although the specific mechanisms for these adverse reactions remain undefined.

Mice administered 60 times the recommended dose of Ca-DTPA developed severe injuries to kidneys, liver, and the intestines, and deaths occurred.⁵ Toxicity was correlated to the total dose and dosing schedule. Fractionated doses increased mortality compared to similar doses given as a single injection. The injuries were believed to result from significant depletion of Zn and Mn, since the same toxicity did not occur when Zn-DTPA was given at the same dose and schedule. These mice data were interpreted to suggest that Zn-DTPA is approximately 30 fold less toxic than Ca-DTPA. Acutely lethal doses of Zn-DTPA were estimated to be 10 g/kg in the adult male mouse.

Safety

Due to the renal excretion of the radioactive chelate, the kidneys are exposed to potentially higher doses of radiation than other organs, which theoretically may lead to increased risk of malignancy. Additionally, because urine is radioactive during chelation there are recommendations to use toilets instead of urinals and to flush several times. Any spilled urine or feces should be cleaned promptly and completely, accompanied by thorough hand washing. Patients being chelated should take special care to dispose of any expectorant or breast milk carefully. After nebulization treatments, patients should be cautioned not to swallow any expectorant. Nebulized treatment is associated with asthma exacerbations.

DOSING AND ADMINISTRATION

If the contamination route is mixed or unknown, then Ca-DTPA should be administered intravenously. The intravenous dose of Ca-DTPA is 1 g in adults and 14 mg/kg up to the adult dose in children under 12 years up to a maximum of 1 g, administered either undiluted over 3 to 4 minutes, or diluted in 100 to 250 mL D₅W, Ringer lactate, or 0.9% sodium chloride, over 30 minutes. On the basis of animal studies, it should not be given more slowly.⁴ Maintaining normal volume status and frequent voiding should be encouraged to dilute the radioactive chelate and minimize exposure to the bladder. If contamination occurred only via inhalation, then Zn-DTPA may be diluted 1:1 with sterile water or 0.9% sodium chloride and administered via nebulization.¹⁶

Although Ca-DTPA is recommended as the initial chelator, Zn-DTPA should be used after the first 24 hours. Although animal studies show a 10 fold increased rate of elimination of Pu with Ca-DTPA compared with Zn-DTPA, trace metals, such as zinc, are excessively removed with continued treatment with Ca-DTPA. After this period, Zn-DTPA given daily at the same dose is recommended for any continuing therapy because of its relatively diminished depletion of trace metals and the absence of liver, kidney, and intestinal injury.

Timing of Administration and Duration of Therapy

Administration of DTPA is recommended to begin as soon as possible, preferably within the first hour following contamination. Historically, about 55% of all patients treated with DTPA required only one dose. The decision to continue therapy should be based on radioassay data. This assessment should include collection of 24-hour urine samples, whole body or chest counting, and close consultation with the hospital radiation safety officer. Assistance is also available from REAC/TS at 865-576-1005; ask for REAC/TS. Current recommendations are to continue chelation until the deposition of contaminant is less than 5% of the maximum permissible body burden for a given contaminant.³

If continued therapy is indicated, then a regimen of Zn-DTPA may begin the day following initiation of therapy. Dosing regimens may include Zn-DTPA 1 g intravenously daily up to 5 days per week for the first week. If continuing chelation therapy is indicated, then a twice a week regimen should be initiated until the excretion rate of the contaminant does not

increase with Zn-DTPA administration.^{15,16} As with the decision to initiate DTPA therapy, any continued treatment must be coordinated with a radiation safety officer. For all patients, data regarding vital signs, adverse effects, and bioassay studies should be reported to the drug manufacturer and also to REAC/TS.

Monitoring

A complete blood count with differential, blood urea nitrogen, serum chemistries and electrolytes, urinalysis, as well as blood and urine radioassays should be obtained prior to initiating treatment. Daily zinc, manganese, and magnesium monitoring should occur as well as supplementation with zinc. During treatment, repeated blood, urine, and fecal radioassays should be run to monitor elimination.

Patients with Chronic Kidney Disease

Although dose adjustment is currently recommended for patients with chronic kidney disease, kidney disease will impair chelate elimination from the body. Hemodialysis might be used to increase the rate of chelate elimination in these patients. Since dialyzed radionuclides will contaminate dialysis fluid, care must be exercised during the procedure as well as in discarding fluid and preparing the machine for subsequent patient use. Consultation with the radiation safety officer (RSO) is recommended to assist with discarding waste material, as well as with the overall chelation treatment of the contaminated patient.

PREGNANCY AND LACTATION

Ca-DTPA is listed as FDA pregnancy category C based on animal data. Mouse studies involving doses up to 10 times the recommended dose for Ca-DTPA did not produce harmful effects, but doses of greater than 20 times the recommended dose produced teratogenicity and fetal death. Zn-DTPA is listed as FDA pregnancy category B, also based on mouse data. Doses up to 31 times the recommended dose were not demonstrated to impair fertility or harm to the fetus. There are no human pregnancy outcome data from which to draw conclusions regarding the risk of DTPA. Contaminated pregnant women are recommended to begin any treatment with Zn-DTPA due to perceived risk for adverse reproductive outcome. However, for pregnant patients with severe internal contamination where the risk to mother and fetus is considered to be high, Ca-DTPA may be considered for a first dose in conjunction with mineral supplements that contain zinc. These chelators do not cross the placental barrier.

There are no studies regarding DTPA excretion in breast milk. However, radiocontaminants are excreted in breast milk. Thus, women with known or suspected contamination should not breast feed. Likewise, there are no data regarding safety in lactating women, and data regarding the use in children are extrapolated.

FORMULATION AND ACQUISITION

DTPA is available as Ca-DTPA or Zn-DTPA as a sterile solution in 5 mL ampules containing 200 mg/mL (1 g per ampule) for intravenous use. It should be stored in a cool, dry place with an ambient temperature of between 59°F (15°C) and 86°F (30°C) away from sunlight. Several manufacturers formulate DTPA for intravenous administration. Five mL ampules are available singly and in 10 packs. Both chelators are maintained in the Strategic National Stockpile.

SUMMARY

- DTPA is a safe and effective means of chelating americium, curium, and plutonium in a contaminated patient.
- Rapid consultation with a radiation safety officer is recommended to determine the type and degree of contamination, as well as the need and duration of any treatment.
- In most cases, Ca-DTPA should be started as soon as possible after a contamination followed by the use of Zn-DTPA if continued treatment is needed.
- Regular monitoring and supplementation of zinc, magnesium, and manganese during therapy is recommended, although the risk of clinically significant depletion is low at therapeutic doses.
- Hemodialysis may be used to increase renal elimination when chelating contaminated patients with kidney disease, although specific data for this use are limited.

SECTION II

POISON CENTERS AND EPIDEMIOLOGY

CASE STUDY 12

History A 60 year-old man with a history of hypertension, coronary artery disease, congestive heart failure, and chronic obstructive pulmonary disease was admitted to the hospital following an emergency department (ED) presentation for shortness of breath. Because no bed was available on the inpatient service, he was boarded in the ED for many hours. The ED physician who is no longer caring for the patient received a call from the laboratory that the patient's serum potassium was 6.8 mEq/L in a nonhemolyzed specimen. A call was placed to the patient's care team, but after several minutes there was no response.

Physical Examination A brief examination was performed, and the following vital signs were obtained: blood pressure, 166/92 mm Hg; pulse, 84 beats/minute; respiratory rate, 22 breaths/minute; temperature, 99.2°F (37.3°C); oxygen saturation, 93% on 4 L oxygen/minute via nasal cannula. The patient was awake and alert with a normal neurologic evaluation, and the chest examination revealed some wheezing and rhonchi and a regular heart rhythm with an S3 gallop. Electrocardiography (ECG) was obtained (Fig. CS12–1).

FIGURE CS12–1. Electrocardiography obtained at the time the serum potassium was reported to be elevated. The ECG shows a sinus rhythm with a rate of 90 beats/min, with normal axis and intervals. Findings consistent with hyperkalemia (Chap. 16) are absent.

Immediate Management The ED physician ordered calcium gluconate (1 g), regular insulin (10 units), and dextrose (25 g) all to be given via the intravenous (IV) route to treat hyperkalemia. Shortly after the nurse administered the medications, the patient was noted to have a generalized seizure and lost consciousness. His pulse was noted to decrease and his QRS complex widened (Fig. CS12–2). The patient's permanent pacemaker captured intermittently, and his blood pressure fell to 80/50 mm Hg. A bolus of 1 L of 0.9% sodium chloride was ordered and the patient was placed on 100% oxygen via a nonrebreather mask. A rapid reagent glucose was obtained and reported as 98 mg/dL.

FIGURE CS12–2. Electrocardiography obtained shortly after the patient had a generalized seizure and loss of consciousness. The ECG demonstrates a wide-complex dysrhythmia with a rate of 75/min, a QRS duration of 160 msec, and an overall morphology suggestive of an idioventricular rhythm. Although pacemaker spikes are seen at a rate of 80/min it is unclear if this impulses captured.

What Is the Differential Diagnosis? The toxic syndrome that is characterized by a rapid onset of a seizure, hypotension, and a wide-complex dysrhythmia was highly suggestive of Na^+ channel blockade. Common Na^+ channel blockers are listed in [Table CS12–1](#) and discussed in [Chaps. 16, 48, 64, and 71](#). None of the ordered medications typically produce this effect. Additional considerations were that the administered xenobiotic would have to be available in an intravenous form and could be potentially confused with hypertonic dextrose since the patient’s glucose was not elevated as would have been expected following a bolus of D_{50}W (Antidotes in Depth: A12).

TABLE CS12–1. Common Xenobiotics That Block Cardiac Sodium Channels

Antidepressants	Antipsychotics
Heterocyclics	Mesoridazine
Tricyclics	Thioridazine
Bupropion	Carbamazepine
Antidysrhythmics	Cocaine
Class IA	Diphenhydramine
Class IB	Lamotrigine
Class IC	Potassium
	Hyperkalemia

Further Diagnosis and Treatment While the nurse was asked to review the medications given, the physician labelled

and saved the syringes used to deliver the original medications and administered a bolus of 2 ampules (44 mEq each) of hypertonic sodium bicarbonate. Within 1 to 2 minutes the ECG returned to baseline, his hemodynamic parameters improved, and his mental status slowly normalized.

The nurse reported that the drawer in the automated medicine dispenser was filled with lidocaine instead of dextrose and, and that the vials looked similar (Fig. CS12–3). The patient may have received a bolus of lidocaine. This was confirmed with a serum lidocaine concentration of 4.9 mg/L taken about 1 hour after the event. Full disclosure was made to the patient and the pharmacy was informed of the error.

FIGURE CS12–3. Bottles of lidocaine and dextrose that were confused with each other.

How Do Medication Errors Occur? Chapters 135 to 141 deal with many issues of poison prevention and safety. This case highlights some of the key issues. System errors such as hospital and ED overcrowding that result in boarding of patients in busy areas remote from their primary care providers where teams turn over at relatively short intervals increase the likelihood of errors. Cognitive errors such as the urgency to treat a critically abnormal laboratory value (hyperkalemia), even in the absence of any characteristic ECG or clinical findings, may have been contributory. Improper filling of the storage device and purchasing of look alike medication vials added to the confusion. Finally, in this case, a simple error of not confirming that the medication that was ordered was the medication delivered, including proper dose and route, was nearly fatal. Fortunately, immediate recognition of the error and appropriate intervention proved to be life saving.

135 POISON PREVENTION AND EDUCATION

Lauren Schwartz

Unintentional poisonings are a global health concern. According to the World Health Organization (WHO) Global Burden of Disease Project, in 2004 approximately 3,346,000 people died worldwide from unintentional poisoning.⁸⁰ Nearly 1 million people die each year as a result of suicide. Approximately 350,000 deaths result from the deliberate ingestion of pesticides. In addition, an estimated 5 million snakebites occur annually.⁸⁰ The WHO has undertaken initiatives in many countries, including the Bahamas, China, Ghana, Lebanon, Myanmar, Senegal, and Trinidad and Tobago to establish Poison Centers (PCs) and raise awareness about poison prevention. Worldwide, data on nonfatal poisoning rates are currently not available, although the increase in poison centers globally may result in improved research and surveillance programs.⁵⁴ This chapter focuses on programs in North America that aim to prevent unintentional poisonings and improve access to PC services.

Healthy People 2020 is a US federal program that outlines the health goals for the nation. These overarching goals are to attain high quality longer lives, achieve health equality and eliminate disparities, create social and physical environments that promote good health and promote quality of life, healthy development, and healthy behavior across all life stages. Two objectives in the Injury and Violence Prevention section relate to poison prevention. Objective IVP-9 is to reduce poisoning deaths and Objective IVP-10 is to reduce nonfatal poisonings.²⁵ Community based public education programs at PCs are designed to help meet these other public health objectives.

LEGISLATION AND POISON PREVENTION

Since the first PC was established in 1953, a number of legislative efforts have improved poison prevention and awareness and reduced the number of unintentional poisonings in children. Public education programs at PCs have been influenced by these federal measures.⁷¹

National Poison Prevention Week

In 1961, President Kennedy signed Public Law 87–319, designating the third full week of March as National Poison Prevention Week (PPW) to raise awareness of the dangers of unintentional poisonings. Each year, during PPW, PCs and other organizations around the country organize events and activities to promote poison prevention.

Child-Resistant Packaging Act

In 1970, the Poison Prevention Packaging Act was passed. This law requires that the Consumer Product Safety Commission (CPSC) mandate the use of child-resistant containers for toxic household xenobiotics. In 1974, oral prescription medications were included in this requirement. A review of mortality data in children younger than 5 years of age shows a significant decrease in deaths after enforcement of the child-resistant packaging legislation.^{61,71,75}

Taste-Aversive Xenobiotics and Poison Prevention

Nontoxic taste-aversive xenobiotics are frequently added to products such as shampoo, cosmetics, cleaning products, automotive products, and rubbing alcohol to discourage ingestion.²⁴ This is done primarily to prevent poisoning in children except in the case of rubbing alcohol, where adults are also targeted. The most common taste-aversive xenobiotics are the denatonium salts, particularly denatonium benzoate (Bitrex, benzyldiethyl [(2,6-xylylcarbamoyl)methyl] ammonium benzoate), one of the most bitter-tasting xenobiotics known. The bitter taste of denatonium benzoate can be detected at 50 parts per billion (ppb). This aversive xenobiotic is used in concentrations of 6 to 50 parts per million (ppm), typically 6 ppm in cosmetic products and ethanol-containing household products and 30 to 50 ppm in methanol and ethylene glycol.^{8,53} Only limited data are available on the usefulness of taste-aversive xenobiotics for prevention of poisoning. Studies using denatonium benzoate added to liquid detergent and orange juice demonstrate that it can decrease the amount ingested by children.^{6,67} However, the degree of taste aversion is not universal. In one study, some children were noted to take more than one sip of denatonium benzoate-containing orange juice.⁶⁷ Taste aversion is partially a learned response. Frequently

young children do not find a bitter taste as offensive as do adults.⁷ It seems unlikely that taste-aversive xenobiotics will eliminate unintentional ingestions in children, because ingestion is required for aversive effects to occur. Taste-aversive xenobiotics may be most beneficial in the prevention of poisoning by toxic and nonaversive xenobiotics, such as ethylene glycol, methanol, paraquat, certain pesticides, acetonitrile, and bromate-containing cosmetics, where more than one or two sips of the product must be ingested to cause significant toxicity. In 1995, Oregon became the first state to mandate the addition of an aversive xenobiotic to ethylene glycol-or methanol-containing car products in its 1995 Toxic Household Products statute. Analysis on the incidence and severity of ethylene glycol and methanol exposures before and after the mandate could not demonstrate any difference in children under 6 years of age.⁴⁹ Taste-aversive xenobiotics should therefore not be substitutes for other poison prevention modalities.

Toll-Free Access to Poison Centers

In 2000, the Poison Control Center Enhancement and Awareness Act (PL 106-174) was enacted with a goal of nationwide access to PCs. A toll-free number (1-800-222-1222) was established in 2001 for all US PCs.⁷⁸ Callers are connected to a regional PC based on the area code and telephone number exchange. **Figure 135–1** displays the national logo incorporated into educational efforts.

FIGURE 135–1. National toll-free number logo.

ROLE OF PUBLIC EDUCATORS IN POISON CENTERS

Poison Center educators encompass a range of educational backgrounds including nurses, pharmacists, health educators, and teachers. The role of the public educator is based on social marketing concepts and encompasses two objectives: health promotion to change behavior, and marketing of the PC.⁶⁹ Public education programs at PCs teach poison prevention techniques (primary prevention) and raise awareness about available services should a poisoning occur (secondary prevention). Education programs may utilize primary or secondary teaching or a combination of both.^{5,27,32,39} Public educators at PCs provide a range of community based programs ranging from workshops and health fairs to producing print materials, videos and or DVDs, and awareness campaigns through public service advertising using radio, television, print, and mass transit venues. Social media in health promotion offers an opportunity to further expand the dissemination of health information to diverse audiences through enhanced communication.⁴⁷ Since underserved groups use mobile handheld devices frequently to access information, cell phones, mobile technology, and online resources provide new ways that educators can disseminate health messages to those in need.

Educators also participate in community health coalitions, working in conjunction with other injury prevention groups such as National Safe Kids, and collaborate with a wide range of community health agencies. Caregivers of children younger than age 6 have often been the most important group to reach with education programs. Educators often work with national programs for families including Women, Infant and Children (WIC), Head Start, and the Red Cross.

By contrast, older adults (individuals older than 65 years of age) have not been a priority population for PC education resources. However, this group represents a large number of fatalities reported nationally to PCs, primarily due to medication errors.^{10,27} Programs for older adults offer an educational opportunity to reach this high risk population. Collaborative programs with the American Association of Retired Persons (AARP), senior centers, and Departments for the Aging offer an opportunity to provide collaborations focusing on poison prevention and medicine safety programs through educational interventions conducted in senior centers, community agencies, and other groups that serve independently living older adults.

The membership of the American Association of Poison Control Center's Public Education Committee (PEC) includes

the educators from PCs across the United States and Canada. The mission of the PEC is to provide poison prevention awareness programs in an effort to reduce morbidity and mortality associated with poisoning. Each year, the PEC provides educational sessions at the North American Congress of Clinical Toxicology. PEC workshops focus on program development, evaluation, grant writing, strategic planning, and other topics of interest to PC educators.²⁷

NEEDS ASSESSMENTS

To develop successful poison education programs, educators must first analyze demographic data, call volume rates, cultural and language issues, and barriers to calling a PC. Geographic information systems (GIS) software offers a way for PCs to map demographic data. The use of this type of software is increasing in public health and can be applied to PC efforts. The coordination of data retrieval from various data entry programs and the use of GIS software by PC staff provides access to call rates by zip codes, counties, census tracts, or congressional districts to be used for planning programs. Health and social services for the targeted community may also be presented using GIS maps. Using GIS for population based programs is recommended for developing social marketing campaigns, health education programs, outreach efforts, and coalition building.⁶⁰ The study of geographic areas with low call rates enhances the potential for targeted and focused educational programs.

Focus groups, surveys, and interviews provide useful qualitative methods for PC educators to identify the perceptions of parents and caregivers about calling the PC. Barriers regarding PC utilization include not knowing the PC number, preference for calling 9-1-1 rather than the PC, fear of being reported to child welfare agencies, concerns with regard to confidentiality, language difficulties, lack of in person contact with health care providers, low self-efficacy, and concerns regarding the cost of the call.^{1,4,9,28,29,65,73} Each of these barriers must be considered and creatively addressed when planning new programs for reaching caregivers of young children. In one study, 51% of caregivers interviewed in a low income urban pediatric clinic said that they would immediately take their children to the emergency department (ED) after a possible poisoning exposure.⁶³ In a separate study, focus group participants stated they would not call the PC in the case of a poison emergency. Their responses ranking was (1) call the pediatrician, (2) go to the ED, (3) read the label, and (4) call a friend after a poisoning exposure.²⁸ A focus group with parents provided information to refine a telephone survey concentrating on hazardous household materials and health risks. Feedback from caregivers resulted in a more concise instrument with more targeted questions. In addition, perceptions of the PC and suggestions for future educational interventions were also gathered from participants.²⁸ Involving the target audience in the development and testing of information is demonstrated to have improved outcomes when disseminating information.⁷²

Follow-up surveys provide a way to analyze factors related to PC access. English-and Spanish-speaking caregivers in Texas were contacted after an ED visit related to a poisoning exposure in a child. Findings showed that more than half had spoken to PC staff prior to the hospital visit. Of those who did not call the PC, 68% claimed prior knowledge of the PC, yet failed to use it. Significant demographic variables associated with a failure to call the PC were Hispanic (schooling in Mexico) and African American ethnicities.³¹ Findings from an ethnographic study of 50 Mexican-American mothers with children younger than 5 years of age demonstrated that none had the PC number in their home.⁴⁶

In person interviews were conducted with parents in the pediatric clinic about poison prevention strategies and awareness of the poison center.^{16,20} A pilot study to determine predictors of storage included acculturation, age, gender, and education among parents found that less acculturated parents were more likely to store medicines and cleaning products unsafely in the home.¹⁶ Another study conducted with 216 parents and caregivers reported that 80% were aware of the poison center services. However, none knew the 800 number specifically, although many stated they had the number in their home. Of the 42 participants (20% of the sample) unaware of the PC services, 57% were non-English speakers.²⁰

In order for educators to plan effective programs with older adults a needs assessment of the perceived barriers and benefits for this target group related to accessing the PC is required. Focus groups conducted with older adults show that most do not perceive the PC as an appropriate service for their concerns, but rather as a service for children and parents. Additionally, the participants expressed a very narrow view of what was considered a poison such as bleach and household products. Similar to caregivers of children, older adults repeatedly state that they would call 9-1-1 in an emergency.¹¹

POISON EDUCATION PROGRAMS

Over half of the 2 million annual calls to PCs nationally involve children younger than 6 years of age.¹⁰ As a result, programs to teach caregivers about primary and secondary prevention techniques have been the major aim of education efforts. Typically, these programs focus on teaching poison prevention (Table 135–1) and raising awareness of PC services. Poison education programs designed to address barriers to accessing the PC through community interventions are reported in the literature. In one study, parents at two WIC centers reported an increased comfort level with calling the PC after a video based intervention.³⁰ Interventions have demonstrated an increase in knowledge about PC messages and

poison prevention in the study groups.^{30,38}

TABLE 135–1. Poison Prevention Tips

- Identify poisons inside and outside the home
- Keep poisons out of reach of children in a locked cabinet
- Keep products in their original containers
- Never keep food and nonfood items together
- Install carbon monoxide detectors in sleeping areas
- Keep plants out of reach of children and pets
- Use child-resistant containers
- Post the poison center number on all telephones and in all cell phones

Interventions Targeting Health Behavior

Unintentional poisonings frequently happen when children are left unattended for a brief period of time (< 5 minutes) and a toxic product in use or recently purchased is left within reach of the unattended child.⁵¹ A qualitative study conducted of 65 parents, some whose children had experienced an unintentional poisoning, showed that poison prevention strategies were not consistently implemented in the home. Recommendations included ongoing parent education to reemphasize that “child resistant” is not “childproof,” and reinforce safe storage of potentially toxic products, particularly those that are often used.²² When knowledge and behavior were measured through telephone surveys conducted 3 months after a poison prevention packet was mailed to families of young children who had experienced a poisoning, caregivers were more likely to have the PC number posted in the home.^{30,79}

The ED presents an opportunity for poison education programs to work with families to prevent further poisoning exposures.¹⁷ An injury prevention program provided to caregivers of young children after a home injury was effective, particularly regarding retention of poison prevention information and the use of safety devices.⁵⁶ The use of a computer kiosk in an ED to provide personalized child safety information including specific advice of poison storage for parents showed increased knowledge scores on follow-up telephone surveys.²³

The effectiveness of poison prevention education for families who called the PC following a potential exposure in a young child was also studied. Poison prevention instructions, telephone stickers, and a cabinet lock were sent to the family one week after the initial call. Follow-up telephone interviews showed that intervention group recipients reported a higher use of the cabinet lock (59%) and were significantly more likely to post the telephone number for the PC (78%) than those in the control group who did not receive any poison prevention materials within 2 weeks of the incident.⁷⁹

Poison education programs developed to address caregiver barriers have also been evaluated. An educational video targeting low income and Spanish speaking mothers was developed and evaluated. Results showed increased knowledge about the services, staff, and appropriate use of the PC compared with a control group that attended the regularly scheduled WIC class.³⁰

Instructor training programs have been designed by a number of PCs to reach leaders or educators of community based organizations to incorporate poison education into their roles for the general population. An evaluation of the “Be Poison Smart” program showed an increase in knowledge and behavior change among service providers after a standardized training session. These reported changes included having the PC number visibly posted and keeping hazardous products out of reach.⁵⁵ Working with community based services such as WIC presents an opportunity to reach the target population. Pretests and posttests administered to WIC staff and public health nurses showed increased understanding about poison prevention and increased awareness of PC services.⁵⁷ Community health workers (promotoras) are involved in health promotion particularly in hard to reach communities. A train-the-trainer model evaluation demonstrated increased knowledge and behavior for teaching healthy homes promotion in the community setting.⁴⁰

Focus group participants identified pediatricians as a trusted source of health information for parents.^{28,65} The AAP includes a poison prevention counseling recommendation as part of The Injury Prevention Program (TIPP). TIPP is a safety education program for parents of children newborn through 12 years of age. The TIPP age related safety sheets include poison prevention advice for parents of children aged 6 to 12 month, 1 to 2 years, and 2 to 4 years.² Each safety sheet encourages parents to call the toll-free number for PCs if the child ingests a potentially poisonous product. It is important that the AAP continues its support for efforts by PCs to prevent childhood poisonings.³⁹ In another study, family practitioners and pediatricians were surveyed with respect to poison prevention counseling for parents. Although more than 80% of both groups reported that this was an important topic, family practitioners were less likely than pediatricians to provide poison information during a visit.²¹

Education programs are designed for school-age curricula. The effectiveness of MORE HEALTH, a program to teach kindergarten and third-grade students about poison prevention, was studied.³⁸ Posttests administered 1 to 2 weeks after the intervention showed increased knowledge in the intervention group of children. Parents of children in the intervention group also self reported that their homes were more likely to be “poison-proofed.”

Recommendations have been made to develop programs targeting older adults, particularly about potential problems with medication use and storage.^{27,36,68} Efforts to teach nursing home staff about potential poisoning exposures are also recommended.³⁶ There has been a shift in the priority of poison education programs to address this target population. An ED study of older adults showed that seniors had poor knowledge of their current medications. In addition, patients taking more medications were less likely to know the proper dose, name, and purpose of the medications.^{14,76}

Community-Wide Interventions

A review of pediatric literature focusing on community based poisoning prevention programs showed that only four studies could be found using poisoning rates as the outcome measure. Additional creative studies to measure community based poison prevention efforts will be essential to determine the importance of these efforts.⁵⁰

In general, mass mailing of poison information is generally not an effective means to increase call volume for poison exposure or information requests nor is it cost effective.^{19,34} Similarly, a distribution of textbook covers with the national logo and PC information to elementary and secondary schools in low PC utilization counties was not an effective method for increasing PC calls.⁸² A hospital mailing that combined primary (poison prevention tips) and secondary (telephone stickers) messages were included in an established family health promotion magazine distributed widely in the PC regional area. This effort resulted in an increased call volume in areas where at least 5% of the residents received the information.³² In addition, another study result in that overall call volume increased by 11.2% after more than 1 million pieces of literature containing the toll-free number were distributed at sites including emergency departments, doctor offices, schools, and pharmacies.³³

An increased number of information calls to the PC was attributed to a campaign developed to raise community awareness.⁷⁰ Media provide a venue for conducting educational activities. Direct mail, radio, television, newspapers, and magazines were incorporated into a media campaign developed to raise awareness in a particular Latino community. A telephone survey conducted pre-and post-media campaign showed an increase in awareness about the PC.¹ Although developing this type of program is often costly compared with other education efforts, the potential audiences are vast. Mass media campaigns are powerful tools used in health promotion and disease prevention efforts.⁵⁸ Research shows that a multilevel approach of media campaigns combined with community-based interventions and health education materials influence health behaviors and raise awareness. Additional factors that contribute to successful mass media campaigns include influencing the information environment to maximize exposure, using social marketing strategies, creating a supportive environment for the target audience to make health changes, and theory based process analyses to permit changes mid-campaign and assess outcomes and subsequent strategies in an iterative manner.⁵⁸ Radio and television news stations often provide a way to broadcast poison prevention messages during PPW and during periods associated with perceived increased risks to a community. Social media is viewed as a communications tool rather than a factor in behavior change. Therefore, a process evaluation strategy is appropriate for measuring reach, context, delivery, and fidelity of application.⁴⁷

Multilingual Populations

Language and culture must be addressed when planning community-based programs. Quantitative and qualitative research examining Latino communities and calls to the PC have been conducted. The findings from interviews with 206 Latino parents at a WIC site showed that 62% had not heard of the local PC and 77% did not know the PC services were free and offered in Spanish.⁷⁴ Two other studies examined the call rates in communities with significant Latino populations. These areas had lower call rates than comparable areas based on demographic and socioeconomic factors.^{15,73} Furthermore, a number of studies demonstrate that Spanish speaking caregivers are less likely to call the PC because of concerns including confidentiality and language barriers.^{1,4,15,29,46} In a study conducted with 100 Mexican-American mothers of children younger than 5 years of age, 32% reported that a doctor or nurse would be the initial contact for health advice.⁴³ Other sources include friends and family (29%), mother, grandmother, mother-in-law (21%), and spouses (17%). Most of the mothers (81%) acknowledged the use of home remedies to treat their childrens' illnesses.⁴³ New immigrant families from Mexico and Latin America are at high risk for poisoning exposures. PC education programs should target populations in communities where the impact has the potential to be consequential.⁶⁶ Caution should be used when planning programs based on census data for demographic information as this data may not reflect the specific population or characteristic under study in community based programs. When ethnicity information is not collected from callers who contact the PC, there are severe limitations to the value of the data.¹⁵

Qualitative research can help to identify cultural issues when planning targeted education efforts. Monolingual Spanish

speaking mothers were more likely to report poor storage of household products and lack of protective placement of plants.¹ Mexican-born mothers of children younger than 5 years of age were interviewed in their homes about poison prevention techniques. Safe storage was clearly a problem in these homes with 64% of homes having bleach stored within reach of children. The presence of multiple families living in the same home further impedes safe storage practices. In this study, families stored all personal products including medications and household cleansing agents with them in their bedrooms rather than in common areas such as the bathroom.⁴⁶

It is important to consider employment of bilingual staff as public educators when attempting to expand public awareness. The benefits of a bilingual educator include the ability to provide programs directly to an audience and eliminate the need for a translator. A lack of bilingual providers was the most significant barrier identified for Spanish speaking women interviewed about injury prevention techniques.²⁶ Recommendations for more effective outreach to Latino populations include television advertisements and distribution of written information at schools, churches, and doctor offices.⁷⁴ Health education programs including mass media campaigns, designed to accurately reflect the cultural identity—language, beliefs, roles—of the targeted population are more likely to be accepted. Storytelling has also been a recommended strategy for health education among many cultures.⁴⁴ When asked to provide suggestions for poison prevention education, responses included Spanish radio and video programs as well as brochures that incorporate culturally appropriate values. Including messages into widely recognized media such as telenovelas should also be considered when developing information dissemination channels. Most parents reported interest in learning from PC staff, doctor, or a teacher.¹⁶

Field testing concepts and materials are important for the development and distribution of appropriate information for multicultural populations. Further work is needed to examine cultural beliefs related to poison prevention use of and access to the PC. It is important to address cultural beliefs related to use of herbal and other complementary medicines.³⁰ New education programs are needed to reach multilingual and multicultural targeted populations communities across the country. Programs may be more successful if individuals trust and view a source as credible, particularly when cultural attitudes and beliefs closely resemble their own.^{16,35,44} In addition, promotoras or community health workers should be considered to deliver primary prevention information in the Hispanic community for building relationships with parents and overcoming cultural barriers.^{16,40}

Health Literacy/Numeracy

Health literacy is defined as “the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.”⁷² Health literacy encompasses the ability to read, understand, and discuss medical information. Research from the US Department of Education shows that only 12% of US English speaking adults have proficient health literacy skills.⁷² Older adults, Hispanic adults, immigrants, those with less than a high school degree or GED, and low income individuals are at highest risk for low health literacy.³⁷ People with low functional health literacy abilities are less likely to understand written and verbal health information, medicine labels, and appointment information.³⁷ This type of health information is often written at reading levels of at least tenth grade or higher.¹⁸ The recommended reading level for written information is sixth grade. Most Americans are able to understand medical information at this level.⁷² In addition to reading level, use of graphics, font style, color, type size, and layout are important components when developing print material.^{18,72} Recommendations for nonprint methods for communicating health information include visuals (posters, fotonovelas, pictographs), action-oriented activities (role-play, theater, storytelling), audiovisuals (videos, DVDs), and improving patient–provider communication.^{16,18,52,72}

Warning and medication labels are often difficult to understand. The inability to read these warning labels in English presents a barrier for safe storage and safe use of medication and products.⁴⁶ Identification of products often includes brand recognition.⁴⁵ Instructions for proper use and warnings may not be understood from the label independent of language.

In order to address medication safety issues, particularly with medication labels, a number of studies have evaluated ways to simplify the information provided. New recommendations for standardized prescription medicine labels incorporate four specific time periods (morning, noon, evening, and bedtime) and plain language techniques on the container.^{76,77} Similarly, recommendations for nonprescription medicine labels have been developed.⁸¹

The effects of health numeracy as a distinct component of health literacy are presented in the literature.^{48,64} Numeracy is an element of health literacy and involves the ability to use numeric information to make effective health decisions in daily life.³ This also includes concepts of risk, probability, and the communication of scientific evidence.^{48,62,64} Health-related tasks including measuring medications, scheduling appointments, and refilling prescriptions rely on applied numeracy skills.^{62,64} Patients managing multiple prescription and nonprescription regimens will lead to potential medication errors.⁷⁶ Educators need to understand the importance of interventions that accurately assess numeracy levels and appropriately address health outcomes. Recommendations for techniques to improve understanding of numeric information include simplifying concepts, using plain language strategies, and utilizing “teach-back” patient understanding strategies.^{3,72}

Applying Health Education Principles to Poison Education Programs

Health education involves planning, implementing, and evaluating programs based on theories and models. These models offer direction for educators with health promotion planning.⁴² There is a need to increase the number of poison educational programs incorporating health education principles. This includes educational efforts designed to reach individuals through community based programs and media campaigns.

Both the Health Belief Model (HBM) and Social Cognitive Theory (SCT) incorporate the concept of “self-efficacy” and are applicable when designing poison prevention interventions and mass media campaigns. Self-efficacy is the individual’s belief that he or she will be able to accomplish the task requested.^{13,18,41,58} Many health educators believe that self-efficacy is necessary to enable behavior change. The SCT suggests that individuals, the environment, and behavior are intimately and inextricably interrelated.⁴¹ The HBM suggests that individuals are more likely to make health behavior changes based on perceived risk susceptibility, severity, potential barriers, and self-efficacy. These decisions are made when actions are seen as potentially more beneficial to the individual than the perceived risks associated with surmounting the current barriers.¹³

In one study, the HBM approach was used as a framework for poison prevention and for the assessment of barriers to PC use. Questions for focus group participants were developed based on the principles of HBM—that is, perceived susceptibility, severity, benefits, barriers, and self-efficacy related to the health action requested. Most of the mothers viewed poisoning as an emergency and felt it was a health concern for their children. Cues to action are also a component of the model and involve discussions about poison prevention or related information. Participants recommended using community based venues and culturally appropriate information to expand awareness about poison prevention and the poison center.⁹

The HBM and SCT approaches were used to develop the questions for focus groups in both English and Spanish. These questions addressed issues related to poison prevention (severity and susceptibility), the services of the PC (including barriers), and suggestions for education. Focus group participants suggested the use of modeling to reinforce real life scenarios in which a mother handles the poisoning emergency with the staff at the PC with a positive outcome.²⁹ As a result, a video was developed addressing these ideas. Two poisoning situations in which a mother calls the center are depicted. One involves home management (ingestion of bleach) and the second involves taking the child to the emergency department (swallowing grandmother’s antihypertensive pill). The video and correlated teaching guides are available in English and Spanish.³⁰

It is important to develop questionnaires that will be accepted and understood by the target population. A Spanish language instrument that addresses home safety beliefs using the HBM framework was developed and tested. Low income, monolingual, Spanish speaking mothers of children younger than 4 years of age were interviewed about perceived susceptibility, severity, barriers, and self-efficacy factors affecting unintentional home injuries including poison prevention measures. Barriers identified include literacy skills and access to bilingual health information.²⁶

The HBM supports the idea that a “teachable moment” may be the ideal opportunity to present poison prevention interventions.^{23,56} People may be more open to health information after experiencing a traumatic experience.¹² Events such as an unintentional poisoning exposure may motivate individuals to behavioral change. Applying HBM principles suggests that individuals will make changes in terms of poison prevention when or if they view the severity and susceptibility of a poisoning to be high in the home. Many languages are enriched by cultural variations that must be incorporated into poison education programs and best practices for outreach. Our goal as educators is to provide efforts using models that have been tested and evaluated for addressing focused community efforts in each population served by the PC.

SUMMARY

- Poison center public education efforts must encompass needs assessments, program development, implementation, and evaluation.
- Focus groups with caregivers of young children conducted across the country have consistently identified barriers to calling poison centers. These include calling 9-1-1, fear of being reported to child welfare agencies, and lack of confidence in handling poisoning emergencies.
- Using health education theories and models, programs should be developed that address these barriers and encourage caregivers to use the services of the PC appropriately.
- Education programs focusing on the needs of older adults and promoting using the poison center as a resource for medicine safety should be designed.
- Cultural, health literacy, health numeracy, and language needs of target populations are important considerations when planning poison education programs.

136 POISON CENTERS AND POISON EPIDEMIOLOGY

Robert S. Hoffman

HISTORY

In 1950, the American Academy of Pediatrics created a Committee on Accident Prevention to explore methods to reduce injuries in young children. A subsequent survey by that committee demonstrated that injuries resulting from unintentional poisoning were a significant cause of childhood morbidity. Simultaneously came the realizations that a source of reliable information on the active ingredients of common household xenobiotics was lacking and that there were few accepted methods for treating poisoned patients. In response to this void, the first poison center was created in Chicago in 1953.¹⁰² Although initially designed to provide information to health care professionals, both the popularity and the success of this center stimulated a poison center movement, which rapidly spread across the country. The myriad of new poison centers not only offered product content information to health care professionals, but also began to offer first aid and prevention information to members of the community.

In the 60 years that have since passed, countless achievements have been realized by a relatively small group of remarkably altruistic individuals. Throughout this time, poison services have remained free to the public, highlighting their essential role in the American public health system. Many of the legislative and educational accomplishments, which are chronicled in [Chap. 1](#), have directly reduced the incidence and severity of poisoning in children.^{98,110,116} Concurrently, the number, configuration, and specific role of poison centers have shifted in response to public and professional needs.^{50,125}

Modern regional poison centers are staffed by highly trained and certified health professionals who are assisted by extensive information systems. Support is provided by 24 hour access to board certified medical toxicologists and consultants from diverse medical disciplines, the natural sciences, and industry. The role of the current American poison center can be best summarized as follows:

- Maintaining and interpreting a database of xenobiotics
- Reducing health care costs related to poisoning through:
 - Providing information and advice to the public to prevent unnecessary hospitalizations following exposure
 - Providing information and advice to health professionals to improve the diagnosis and care of patients who present to health care
- Collecting epidemiologic data on the incidence and severity of poisoning
- Integrating epidemiologic data as part of the public health surveillance system
- Educating health care professionals on the diagnosis and treatment of poisoning
- Contributing to the science of toxicology

In the past, poison centers were evaluated based on number of incoming calls and measures of community awareness. Current emphasis should be placed on evaluating health outcomes such as admissions to the intensive care unit, length of stay in hospitals, and total health care expenditures. One crucial test of the utility of modern poison centers will be their ability to help reverse the current trend in the United States of increasing adult mortality from prescription drug poisoning.⁶⁷ This chapter explores some of the critical roles of US poison centers and attempts to offer a vision of the future. An overview of the composition of poison centers worldwide can be found elsewhere.⁹⁶ Unique issues facing poison centers in other countries are discussed in [Chap. 137](#).

MAINTAINING AND INTERPRETING A DATABASE OF XENOBIOTICS

The first toxicology database created in the United States was a set of cumbersome 5 × 8-inch index cards produced in the 1950s by the US National Clearinghouse of Poison Control Centers.¹⁰² When it grew to include more than 16,000 cards, the sheer volume of space required to store this information, and the extensive time necessary to manually search these cards, created the necessity of a central repository, such as a poison center. As available information grew, a rapid expansion of

information technology occurred, and the unwieldy index card database was privatized and transformed into microfiche. Although this resource was physically smaller, specialized equipment was required, and a search was still time consuming. Numerous encyclopedic and clinical textbooks were written to supplement the database and provide resources for the office or the bedside. With the growth of the computer age and the Internet, the computer program known as POISINDEX was established to replace the microfiche format as the major source of data on the contents of innumerable household and industrial products, drugs, and plant and animal xenobiotics. POISINDEX also provides uniform management strategies for many potentially toxic exposures. Over the years many proprietary competitors to POISINDEX such as TOXINZ and TOXBASE have gained recognition as valuable tools. Additionally, open source programs such as WIKITOX provide free information to both health care professionals and members of the public.

With this evolution of information technology, poison centers are no longer perceived as the sole guardians of toxicology information. Although these services are still essential for the public at large, and those professionals away from their computers or smart phones, a predictable decline in poison center utilization has paralleled this growth in availability of information. A 1991 study in Utah demonstrated that 82.6% of emergency physicians who had POISINDEX available in their institutions no longer routinely consulted the poison center.²⁷ A similar 1994 New York study suggested that 76% of physicians who had POISINDEX in their emergency departments (EDs) perceived that this decreased their own use of their poison center.¹²¹ These studies suggest that poison centers were more likely to be called for patients with acute and symptomatic overdose and less likely to be contacted for chronic toxicity, asymptomatic patients, and adverse drug reactions.

An initial analysis might suggest that this is an acceptable trend for health care professionals in that it both allows physicians to respond more rapidly to patient needs and for poison centers to be more available to those individuals, especially non-health care professionals, who do not have access to this information system. In fact, one regional poison center model demonstrated that an integrated voice response (IVR) system effectively reduced human interactions for medication identification by more than one-half.⁷⁵ By extension, it might be suggested that both the public and health care professionals can easily access the same information as poison specialists, making the human interaction nearly obsolete. However, this practice of “not calling” not only undermines the efforts of poison centers to gather epidemiologic data (see later) but also creates an understanding gap. In other words, the interpretation of the data is as essential (or more essential) than the data itself. For example, some commonly used sources of toxicology information such as the Physicians’ Desk Reference and material safety data sheets occasionally provide information that may be inaccurate, potentially misleading, or severely limited.^{19,56,87} Likewise, reviews of drug interaction programs designed for mobile devices demonstrated significant variability between individual programs and superiority of larger online resources.^{5,37,94,97} Although POISINDEX routinely provides more accurate information regarding overdose, it is only updated quarterly, cannot be expected to adapt to ongoing epidemiologic trends such as regional variations in substance use, and is incapable of judging adequacy or communications or the subtleties contained in natural language.

The best source for essential new information is skilled professionals who specialize in poisoning. In addition, because most databases are designed to provide information about known entities, they perform poorly when dealing with unknown and unclear scenarios—especially long and complicated differential diagnoses. For example, consider the case of a clinician caring for a lethargic child whose only medication is Zantac syrup. After the other causes of altered mental status have been excluded, the clinician considers drug toxicity. Consultation with standard references suggests that altered consciousness would not be expected with use of this medication. However, a certified poison specialist at a regional poison center recognizes the potential for drug error, has the physician review the syrup bottle in question, and then calls the pharmacy where the drug was provided. The poison specialist learns that although the prescription was written for ranitidine (Zantac), the bottle actually contains cetirizine (Zyrtec syrup), which could account for the child’s symptoms.

Thus, although originally designed as providers of information, poison centers are in reality valued consultants, with staff members who not only provide content information but also interpret clinical material and link both to appropriate management strategies. This goal can only be achieved through rigorous training and certification and recertification criteria designed to provide valued up to date interactions with health care professionals. Access to computer programs can never be considered a substitute for a thoughtful human analysis. Computers do not recognize anxiety, inappropriate questions, and other subtle issues that can only be appreciated with human interactions.

Another illustrative example of the value of poison centers can be drawn from the use of flumazenil for benzodiazepine overdose (Chap. 74 and Antidotes in Depth: A22). Although it may easily be determined by anyone capable of using a resource that flumazenil is an antidote for benzodiazepine overdoses, many subtle characteristics of the patient or the overdose often contraindicate its use. A prospective study determined that when flumazenil was used before consultation with the poison center, contraindications were present in 10 of 14 (71%) cases, resulting in one serious adverse event.²² In the study mentioned earlier, although physicians with access to POISINDEX were less likely to call the poison center, 86.7% still felt that using the poison center to gain access to a physician toxicologist was a valued resource.²⁷ Many poison centers are linked with centers for poison treatment, which are health care facilities that can provide both bedside consultation and unique diagnostic and therapeutic interventions for a subset of patients with severe or complex poisoning.¹ The benefits of consultation are discussed later in Health Care Savings.

PROVIDING INFORMATION AND ADVICE TO THE PUBLIC AND TO HEALTH PROFESSIONALS

In 2011, poison centers in the United States interacted with the public and health professionals more than 3.5 million times.¹⁸ While the financial value of these interactions will be discussed in the section on health care savings below, two major limitations to the success of poison centers were highlighted by recent studies. The first, which should be intuitively obvious, stems from the fact that poison centers are remote from the patient and can, therefore, only make decisions based on the information provided to them. Although poison information specialists are highly skilled and use a variety of communication styles to obtain the most accurate information,⁴⁸ the quality of the information impacts on the utility of their recommendations. The greatest concern often is the estimation of the actual dose of an exposure. In a 3.5 year study of all children referred by a poison center to a health care facility for the determination of the presence of either a methanol or an ethylene glycol blood concentration because of the history of an exposure, only 21 of 102 children had a measurable concentration.⁷⁸ While this has serious limitations on the interpretation of poison center data,⁶² the implications for clinical care are even greater. Likewise a human volunteer study demonstrated that adults are totally incapable of determining residual volumes in containers or describing the actual volume of semiquantitative descriptors such as “a small mouthful” or “a gulp.”⁶¹ Because critical decisions are made based on the history of ingestion or amount ingested, a clear challenge for poison centers is to develop methods to improve the accuracy of this information. Digital imagery may provide a useful method of assisting caregivers with determination of residual container volumes by allowing specialists to clarify container sizes and residual volumes.

The second challenge involves the gap that exists between recommendations that are made by poison centers and those that are accepted. Two recent papers highlight this concern. In a 7 year analysis of poison center recommendations for the administration of high dose insulin and glucose therapy, the recommended treatment was actually administered only 50% of the time.⁴⁹ Similarly, in a 5.5 year study of calcium channel blocker and β -adrenergic antagonist overdoses at a different poison center, high dose insulin and glucose therapy was only started in 42% of cases where it was recommended, and intravenous fat emulsion was only given in 33% of cases where it was recommended.⁴¹ Because both these therapies are considered effective and potentially life saving (Antidotes in Depth: A17 and A20), poison centers need to evaluate the reasons these recommendations are not accepted and explore methods to improve communication with providers. The use of on-site medical or clinical toxicology faculty liaisons may help reduce these gaps.

COLLECTING POISON EPIDEMIOLOGY DATA

In 2007, the US Centers for Disease Control and Prevention (CDC) reported that poisoning fatality surpassed both motor vehicle crashes and firearms to become the leading cause of injury related fatalities.⁹³ This trend has continued and is largely influenced by an epidemic of prescription opioid abuse.⁶⁷ Understanding the evolving trends in poisoning is essential to the development of enhanced surveillance, prevention, and education programs designed to improve medication prescribing, drug safety, and to reduce unintentional poisoning. Although data can be analyzed from numerous sources, such as death certificates, hospital discharge coding records, and poison centers, it is essential to recognize the biases that are inherent in each of these reports. Because not all significant poisonings result in either hospitalization or fatality, data from poison centers appear to offer a unique perspective.

Unfortunately, the term “poisoning” is often defined differently and therefore may be confusing. In this text, “poisoning” is used to denote any exposure to any xenobiotic (drug, toxin, chemical, or naturally occurring substance) that results in injury. Yet the data collected and disseminated by poison centers are defined by the term “exposures.”^{13-18,76,117-119} Many exposures are of limited toxicologic consequence either because of the properties of the xenobiotic involved, the magnitude or duration of the exposure, or the uncertainties regarding whether an actual exposure has occurred. Therefore, data collected by poison centers represent a limited and ill-defined measure of poisoning.

The situation is further confounded by multiple biases that are introduced by the actual reporting process, which first and foremost is voluntary and passive. Because most calls concern self reported data from the home and are never subsequently confirmed, a significant percentage of the data generated to date may actually represent only potential or possible exposures, which can introduce large statistical errors into the database. This is highlighted by the 21 of 102 children who tested positive for a toxic alcohol discussed above.⁷⁸ Despite the fact that only those 21 children were definitively exposed and potentially poisoned, all 102 were entered into the database as exposures. If these figures are representative of the rest of the data set, then they suggest that an actual ingestion does not occur in the vast majority of reported unintentional exposures in children. However, they do emphasize that in all of the cases a toxin was in an unacceptably close proximity to a child. Also, current events, hoaxes, and media awareness campaigns all may influence self-reporting rates.⁸¹ Furthermore, to report a possible exposure a caller must have a telephone, probably speak English, and have some degree of health literacy and numeracy.^{80,115} Although telecommunications devices for the hearing impaired and translation services exist, they are rarely used. Enhancement of technology to facilitate the accurate exchange of

information between poison specialists and either hearing impaired callers or those who do not speak English is essential to the success of poison centers. While text message is an interesting option, preliminary data suggest that text messaging encounters take way too long to be productive.⁹⁹ Another would be to entertain more active reporting systems automatically triggered directly by hospital laboratory values. Such a system would explore cognitive behavior of clinicians around reporting and develop a true understand of the epidemiology.

Under the present passive system, when hospitals report exposures to the poison center, a comparison of the hospital chart with the poison center record shows good agreement, demonstrating an accurate exchange of information.⁶⁴ Unfortunately, a reporting bias similar to that described above is well recognized regarding professional utilization of poison centers and has been called the Pollyanna phenomenon.⁵⁷ For example, in the spring of 1995, poison centers in the northeast United States began to receive numerous reports of severe psychomotor agitation and other manifestations of anticholinergic syndrome in heroin users. In the initial phase of the epidemic, most of the callers requested assistance in establishing a diagnosis, determining possible etiologies, and raised questions regarding treatment with physostigmine.⁵⁸ Although the epidemic continued for many months, once the media announced that the heroin supply was tainted with scopolamine, and clinicians became familiar with the indications and administration of physostigmine, call volume decreased. Stated simply, health care professionals are less likely to call the poison center regarding issues with which they are familiar, are of little clinical consequence, or are not recognized as being related to a poison. Thus, a bias is introduced that results in a relative over reporting of new and serious events and a relative underreporting of the familiar or very common, unrecognized poisoning, and those exposures or poisonings that are apparently inconsequential. Numerous comparisons support this contention. Investigators who rely on published data from poison centers as a sole source of epidemiologic information demonstrate a failure to understand the complexity of poisoning data and the aforementioned consequential limitations of poison center–derived data.

Fatal Poisoning

A 4 year study compared deaths from poisoning reported to the Rhode Island medical examiner with those reported to the area poison center.⁷⁹ Not surprisingly, the medical examiner reported many more deaths: 369 compared with 45 reported by the poison center. Although most of the cases not reported to the poison center were victims who died at home, were pronounced dead on arrival to the hospital, or those in whom poisoning was not suspected until the postmortem analysis, 79 patients who subsequently became unreported fatalities were actually admitted to the hospital with a suspected poisoning. In 10 of these cases, the authors concluded that a toxicology consultation might have altered the outcome. Examples of interventions that, if recommended and performed, might have resulted in a more favorable outcome included the proper use of antidotes such as naloxone for an opioid overdose, N-acetylcysteine for acetaminophen (APAP) poisoning, the cyanide antidote kit, sodium bicarbonate for a cyclic antidepressant overdose, hyperbaric oxygen for carbon monoxide poisoning, hemoperfusion for a theophylline overdose, and hemodialysis for a lithium overdose. While the xenobiotics may have changed since this study was performed, the fundamental principles highlighted remain relevant.

Likewise, when medical examiner data were analyzed in Massachusetts, more than 47% of poison fatalities had not been reported to the poison center.¹⁰⁷ A California study evaluating 358 poisoning fatalities reported to the medical examiner showed that only 10 poison center fatalities were reported over a similar time period, demonstrating an even more consequential reporting gap.⁷ Once again in this study, whereas the majority of underreporting was with respect to prehospital deaths (68%), only 5 of 113 hospitalized patients who ultimately died were reported to the poison center. Additionally, a cross-sectional comparison of national mortality data with poison center data for agricultural chemical poisoning demonstrated a similar trend of underreporting to poison centers of seriously poisoned admitted patients who became fatalities.⁷² Furthermore, when data for an entire year from the National Center for Health Statistics were compared with the same year of data from the American Association of Poison Control Centers (AAPCC), it was apparent that the AAPCC data captured only about 5% of annual poison fatalities.⁶³

More recent analyses have highlighted a remarkable trend. When 11 states evaluated trends in poison-related mortality from 1990 to 2001, an average increase of 145% was noted.¹⁰⁶ A more comprehensive investigation of the National Vital Statistics System accessed via the CDC's Web-based Injury Statistics Query and Reporting System database demonstrated a 5.5% increase in injury related mortality from 1999 to 2004. Mortality from poisoning accounted for 61.9% of the increase in unintentional injury, 28% of the increase in suicide, 81.2% of the increase in death from undetermined intent, and more than half of the total increase injury-related mortality.⁹³ As of 2004, death from poisoning surpassed firearms and became the second most common cause of injury-related fatality. While most of the fatalities are in adults, a review of the entire 2010 AAPCC database only found 74 reported fatalities in children.²³ Focusing on poison center data alone would produce the erroneous assumption that poisoning-related fatalities were not a significant public health concern. In actuality, poisoning is a significant concern in that other programs designed to reduce deaths from motor vehicle crashes and firearms have been largely successful whereas decades have gone by without a major intervention targeting poison related fatality.

It is logical to assume that similar disparities exist regarding the reporting of nonfatal poisonings. The resultant gap in public health data needs to be addressed through improved definitions, epidemiology, reporting, and analysis of poison-

related data systems. This inequity has developed through a long-standing tradition of poison centers to focus attention and concentrate on the largely benign exposures in children. The emphasis needs to be redirected toward seriously ill poisoning, utilization of the intensive care unit, and other markers of actual poisoning rather than health care utilization for benign events. The necessary data for such an evaluation may already exist, but the challenge will be in linking the data sets to provide a meaningful analysis.

Nonfatal Poisoning

An outreach study in Massachusetts determined that hospitals geographically close to a poison center reported their cases almost twice as often as hospitals remotely located (46% vs. 27% of total cases).²⁸ Additionally, the authors noted that private physicians were less likely to report cases than residents in training. A one year retrospective review demonstrated that only 26% (123 of 470) of poisoned patients who were treated in a particular ED were reported to the poison center.⁵⁹ Interestingly, only 3% of inhalational exposures were reported, compared with 95% of cyclic antidepressant ingestions. The authors also noted, as suggested above, that reporting decreased when comparable exposures occurred over a short period of time. Finally, in the physician survey study cited earlier, physicians reported that they would “almost never” contact the poison center for asymptomatic exposures (62.9%), chronic toxicity (50.4%), or simply to assist in establishing a reliable database (90.2%).²⁷ This statement is most likely accurate even in jurisdictions in which the reporting of all or select exposures is incorporated into public health laws.

Occupational Exposures

Xenobiotic exposure occurs commonly in the workplace. As a result of the long-recognized association between occupational exposure and illness, several federal and state government funded agencies, such as the National Institute for Occupational Safety and Health, Occupational Safety and Health Act, and the Agency for Toxic Substances and Disease Registry (ATSDR), exist to prevent occupational illness, to educate the public, and to collect data on exposures to occupational xenobiotics. Legislation provides for mandatory reporting in some instances and offers workers job protection for voluntary reporting. Poison centers also provide information on occupational exposures and collect data. Once again, there are discrepancies between the poison information data and the data collected by governmental agencies. A six month survey in California noted that only 15.9% of the occupational cases reported to the poison center were captured by a state occupational reporting system.⁹ The most common occupational toxicologic illness—dermatitis—was even further underrepresented in these cases. A follow-up study by the same authors demonstrated that more than one-third of calls came directly from the individual worker, 70% of whom were unaware of the link between their occupation and their symptoms.⁸ Although these data suggest that poison centers can provide substantial assistance following occupational exposures, one author expressed concern, noting in a follow-up study that the poison center failed to provide an adequate epidemiologic assessment in that it did not identify an average of 12 other people per workplace who were also potentially exposed in addition to the index case.¹¹ A 1999 survey of poison centers concluded that “responses to work-related calls are inadequate” and suggested that written protocols might be helpful.¹²

Adverse Drug Events and Xenobiotic Errors

Although the actual numbers are a source of controversy, data suggest that a striking number of adverse drug events (ADEs) occur each year in the United States, with many resulting in death.^{20,31,77} The ease of 24 hour telephone access, combined with the ability to consult with a health professional, make poison centers ideal resources for reporting of ADEs.³⁰ Yet, more than 76% of physicians surveyed stated that they would “almost never” contact the poison center regarding adverse drug events.²⁷ Moreover, 30 of the 56 (53.6%) poison centers surveyed stated that they had not submitted any of their ADE data to the US Food and Drug Administration’s MedWatch program.³⁴ Many of the other centers reported only partial compliance with the MedWatch system.³⁴ Biases may lead to disproportionate reporting of adverse events related to newer drugs skewing the interpretation of the data. For example, although bleeding may occur from both coumadin and dabigatran, it is easy to believe that reports would be more likely to be generated for the newer drug.

Prescription drug errors are another source of potential poisoning. Retrospective review of poison center data suggests that many of these errors are reported. In one report, the poison center provided valuable feedback to pharmacists and physicians about these errors. Ideally, reporting to the state board of pharmacy would assure that proper surveillance and counseling continue. The poison center would seem to be ideally suited to perform this function.¹⁰⁴ Unfortunately, while pharmacists are ideally positioned to identify prescribing errors, data suggest that pharmacist utilization of poison centers is poor.²

Drugs of Abuse

Poison centers also collect data on exposures to drugs of abuse and misuse. These data consist largely of calls for

information from the concerned public and reports of overdose requiring health care intervention. Although ethanol, tobacco, and caffeine are the most common xenobiotics used in society, these cases are rarely reflected in poison center data, with the exception of unintentional exposures in children. In fact, because most substance abuse does not result in immediate interactions with the health care system, other databases such as the National Institute of Drug Abuse Household Survey (now referred to as the Monitoring the Future Study) might better reflect substance abuse trends. Yet even this database has significant limitations.^{6,54} Because poison centers are more focused on immediate health care effects of exposures, it could be argued that only those cases in which health care interaction is required are of value in the database. Since poison centers collect data in real time, centers are ideally positioned to report on emerging trends and sentinel events. Recent examples include poison center experiences with trends opioid abuse in teenagers,^{51,111} bath salts,⁸⁸ synthetic cannabinoid receptor agonists,⁸⁹ and adulterated cocaine.¹¹²

Grossly Underreported Xenobiotics

As discussed previously, there is little doubt that ethanol and tobacco are the most common xenobiotics intentionally used in our society. Although their toxicologic manifestations can be acute and severe, chronic subclinical poisoning often goes unnoticed for many years. Similarly, more than 500,000 American children have lead concentrations above 10 µg/dL and polychlorinated biphenyls can be found in countless adults and children. We must remain cognizant of these large-scale exposures, such as bisphenol A, when we read that plants, cleaning products, and cosmetics comprise the most common exposures to xenobiotics¹⁸ are the most commonly “reported” exposures.

Integrating Epidemiologic Data as Part of the Public Health Surveillance System

With the current limitations of the poison center data, it should be clear that neither the numerator nor the denominator of the actual number of poisonings can be easily appreciated. However, analysis of these data for trends may be more useful because the inherent biases involved in poison center reporting are probably consistent over many years. Increasingly, poison center data are being used as part of surveillance and prediction models,^{46,123} often that extend beyond poisoning to other public health concerns.¹⁰⁵ Rapid reporting in collaboration with the CDC highlights an essential partnership.^{38,55,89} Efforts should be directed to encourage reporting to poison centers by such enhanced access methods as Web-based forms for passive reporting, a direct interface between laboratory and hospital databases that actively transmits data to poison centers, and linkages to other agencies that collect reports of poisoning such as state and local health departments. Additional resources should be directed at improved case definitions (distinguishing asymptomatic exposure from poisoning) and integration with other essential databases such as MedWatch, the National Vital Statistics System, and the National Center for Health Statistics.

Despite its limitations, poison center data have significant utility. It is often an exposure rather than an actual poisoning that provides the impetus for contact with health care. For those exposures that are unlikely to be consequential, the poison center can intervene to prevent potentially harmful attempts at home decontamination and costly unnecessary visits to health care professionals. Interaction with parents at a time of perceived crisis also provides a “teachable moment” (Chap. 135) that may help prevent a more consequential exposure in the future. For those exposures that may result in poisoning, the period of time immediately following exposure is an ideal moment to initiate first aid measures designed to prevent or lessen the severity of poisoning. For both of these reasons the cost, benefits, and efficacy of poison centers especially regarding home calls must be measured in terms of exposures and not poisonings.

HEALTH CARE SAVINGS

When visits to pediatric EDs for acute poisoning were analyzed, one study demonstrated that 95% of parents had not contacted the poison center before coming to the hospital and 64% of those children required no hospital services and could have therefore profited from a poison center interaction.²⁹ By contrast, when parents called the poison center first, fewer than 1% sought emergency services afterward. When 589 callers to one poison center were surveyed, 464 (79%) stated that they would have used the emergency care system if the poison center were unavailable.⁶⁹ In a similar study, 36% of callers would have selected a more costly alternative if the poison center were unavailable.¹⁰ Likewise, when primary care givers were surveyed, over 80% said that they would activate 9-1-1 if there were no poison center.³ Poison center data confirm that approximately 75% of reported exposures that originate outside of health care facilities can be safely managed onsite with limited telephone follow-up. Suggesting simple techniques or reassurance can successfully reduce hospital visits for patients who typically call poison centers which, as defined, may only represent a potential exposure. The use of established protocols, especially for unintentional exposures in children clearly reduces emergency department referral rates.⁶⁰ These interactions can be followed by distribution of simply written prevention literature to improve use and retention. Unfortunately, this approach is less applicable to adults and the population as a whole.

Limited data suggest that direct bedside consultation and care help reduce length of hospital stay and health care

costs.³⁶ Yet poison centers operate remotely. In one assessment, consultation with a poison center reduced length of stay by nearly 3 days.¹¹⁴ Similarly, when the poison center was consulted for patients already in the hospital, length of stay and costs were reduced by 1.9 days and nearly \$5000.²¹ This experience has been replicated outside the United States where poison center consultation resulted in a decreased length of stay of more than 3 days, respectively.⁵² Strongly encouraged or mandated interactions with poison centers might help reduce the cost of health care, hospital overcrowding, and access to limited resources such as antidotes and hemodialysis.

The national average cost to the poison center for a single human exposure call is on the order of \$35.¹²⁵ A federally funded study concluded that, in one year, poison centers reduced the number of patients who were treated but not hospitalized by 350,000 and reduced hospitalizations by an additional 40,000 patients, for a cost savings of more than \$3 million in 1996 dollars.⁸⁶ Each call to a poison center prevented at least \$175 in subsequent medical costs, providing strong theoretical evidence to support the cost efficacy of poison centers. In fact, two natural experiments support these calculations. In 1988, Louisiana closed its state sponsored poison center. During the year that followed, the cost of emergency medical services for poisoning in Louisiana increased by more than \$1.4 million. This additional expenditure represented a greater than threefold increase above the operating cost of that center.⁷¹ Similarly, because of financial disputes in California, direct access to the San Francisco poison center was electronically restricted for one major county, with a telephone recording referring callers instead to the county 9-1-1 system for assistance.⁹⁵ The result of each blocked call was to increase health care costs by approximately \$33. Moreover, these calculations cannot account for the unmeasured benefits to society from poison center interventions that reduce waiting times for ambulance availability and hospital treatments because of lower volumes, money saved by the prevention or reduction of injury from early intervention, or lives saved by enhancing access to or utilization of the health care system for seriously poisoned patients. In El Paso TX, cooperation between emergency medical services and the poison center was able to reduce ambulance dispatches by 1750 over 5 years.⁴ Overall estimates place the rate of return for poison center funding between 11 and 36:1.^{66,108}

However, many barriers prevent a person from calling a poison center, including lack of familiarity with its available services, intellectual and cultural factors, language difficulties, and confidentiality concerns.^{35,70,80,115} Epidemiologic studies demonstrate that areas of increased population density, such as major urban communities, with high percentages of minority inhabitants have lower utilization of poison center services.¹¹³ Additional barriers include the absence of caregiver comfort with the extensive personal contact provided by the health care system and a concern regarding implications of child abuse or neglect when reporting to agencies such as poison center, many of which have governmental ties.¹⁰³ Data demonstrate that public educators can help overcome some of these barriers.¹⁰⁹ One good example of an effort to overcome reporting barriers was the institution of a single national toll-free number for poisoning (1-800-222-1222). Although it is clear that this intervention improved access and increased total calls to the poison center,⁷⁴ it has yet to be determined if this has altered the patterns of use.

PROVIDING EDUCATION FOR THE PUBLIC AND HEALTH PROFESSIONALS

Poison center staff work closely with physicians, community health educators, community support groups, and parent–teacher associations to develop poison prevention activities.⁸² Table 136–1 lists common strategies advocated to prevent poisoning. Poison centers are also actively involved in enhancing training programs for paramedics,⁴⁷ medical students,⁶⁸ pharmacy students,⁴⁰ and resident physicians,^{40,91,122} and are an integral part of postgraduate training programs in medical toxicology fellowships.

TABLE 136–1. Common Strategies Advocated to Help Prevent Poisoning

All xenobiotics should be kept in their original containers. Food and drink containers should never be used for the excess of a xenobiotic.
Never store xenobiotics in unlocked cabinets under the sink. Apply locks to medicine cabinets that are within the reach of a child.
In the absence of a lock, the more toxic xenobiotics should be stored on the highest shelves.
Xenobiotics should never be left in the glove compartment of the family car.
Parents should buy or accept medication only if it is in a child-resistant container.
Medication should be considered as medicine, not a plaything and certainly not candy.
Adults should not take their medications in front of children:
This will limit exposure to drug-taking role models that may become objects of imitative behavior.
Unused portions of prescription medications should be discarded in a manner consistent with local environmental

protection guidance.
Activated charcoal should be readily available in the home for use if directed by a poison specialist or clinician.
Children who have ingested a poison will do so again within a year. These children should receive an enhanced level of supervision.

As stated previously, there is an inherent risk in both enhanced public and professional education programs. Currently, the decreased telephone utilization of a poison center could be both the result of a decrease in the incidence of exposures or poisonings or an enhanced understanding of the prevention, diagnosis, and treatment of poisoning. Although education should never be viewed as detrimental, programs must include an emphasis on the continued use of poison centers to assure access to most current information in a rapidly changing discipline that only develops through an ongoing dialog between health care professionals and poison specialists. In actuality, as a result of the ongoing analysis of incoming calls, the knowledge base has the potential to change as rapidly as the calls are reported. This is far more rapid than can occur in any published literature or electronic database. Thus, additional emphasis should be applied to routine utilization of the poison center as a public health tool to improve the accuracy of epidemiologic data. Reporting of rare or suspected events can serve as sentinel efforts that help identify consequential adverse drug opportunities long before normal postmarketing surveillance tools identify areas of concern.

On the other hand, outreach programs that advise the public to access free services for inconsequential events can easily overwhelm an already stressed system of responding to incoming calls by demanding an immediate response to the less serious calls in an appropriate time frame. Public education and public health must both be considered to assure that poison centers are staffed with the appropriate number of skilled individuals to respond not only to daily events, but also to address surges in calls that may be the result of true epidemics or responses to media announcements. Increasing calls to demonstrate increased utilization offers no public health advantage if the utilization is inappropriate or if seriously ill or potentially ill callers lose access to timely responses.

DEVELOPMENT OF FUTURE PUBLIC HEALTH INITIATIVES

The initial public health efforts of poison centers focused on attempts to alter product concentration and to enhance product labeling and packaging. These clearly beneficial endeavors should continue and must evolve. However, current events have also increased poison center activities in preparedness for mass gatherings and disasters resulting from radiological, biological, and chemical terrorism.^{53,73} Additional links with governmental agencies such as the CDC and ATSDR will expand the role of medical toxicology in community health. The need for 24 hour rapid access to centralized information, existing data entry and retrieval systems, and links to experts in medical toxicology and emergency medicine helps to place poison centers in critical roles in both local and national initiatives. Important contributions have included development of triage and treatment protocols^{24-26,32,33,39,43,60,83-85,90,92,100,101,120,124} and assessments of antidote supplies.^{42,44,45} Table 136-2 summarizes initiatives that require creation or enhancement to improve poisoning epidemiology data. Many of these are discussed extensively in a report from the Institute of Medicine.⁶⁵

TABLE 136-2. Goals for Improving Poisoning Epidemiologic Data^a

- Identify and remove barriers to reporting
- Create multiple methods of reporting:
 - Telephone, instant messaging, facsimile, Internet based, or e-mail
- Simplify communications devices for the hearing impaired
- Allow rapid access to translation services
- Enhance awareness of the public health role of poison centers
- Enhance education of caregivers and health care professionals
- Establish public health legislation requiring professional reporting of exposures
- Distinguish possible exposures from actual exposures to improve the integrity of the database
- Create a category for unconfirmed exposures in the database and encourage its use
- Divide confirmed exposures by certainty:
 - Confirmed by history
 - Confirmed by physical examination
 - Confirmed by quantitative and qualitative laboratory analysis
- Integrate the American Association of Poison Control Centers database with other databases (such as the ICD and “E” code systems) and utilize a standardized data collection instrument
- Automatically interact with hospital and commercial laboratories
- Uplink pharmacy adverse drug event reports, hospital discharges, public health department reports (similarly available with lead screening programs), fire departments and hazardous materials responders, industry workplace exposures,

death certificates, and drug abuse monitoring systems
Provide real-time analysis of incoming data to identify emerging trends
Enhance the speed of data collection and reporting
Mandate the use of accepted epidemiologic and statistical analyses of data
Provide rapid and regular feedback to primary reporters
Issue timely analyses and reports

^aSome of these efforts are either completed or partially completed, but may need refinement over time.

SUMMARY

- Public education efforts help reduce the likelihood of exposure.
- Provision of basic management advice helps to diminish the consequences of a poisoning once an exposure has occurred.
- Reassurance and proper basic management help to curtail unnecessary utilization of expensive health care.
- Interactions with health care professionals streamline the care of poisoned patients saving hospital days and health care expenditures.
- Collaboration with public health authorities will identify, inform, and help mitigate the consequences of ongoing toxicologic events.
- Data on exposures have been effective to create legislation to further limit poisoning by altering contents or improving packaging or labeling.

137 INTERNATIONAL PERSPECTIVES ON MEDICAL TOXICOLOGY

Sari Soghoian

Poisoning is a worldwide problem, but the major effects are felt in the developing world. At least 250,000 to 350,000 people die every year from acute pesticide poisoning,⁷² and an estimated 20,000 to 94,000 humans die each year from snake bites,⁹⁷ the vast majority of whom lives in rural farming areas of lower and middle income countries. Hundreds of thousands of people are affected by groundwater arsenic contamination in Bangladesh and India,¹⁴⁹ and outbreaks of poisoning from contaminated food⁴⁰ and environmental pollution from poorly regulated industrial activity^{49,135} affect whole communities throughout the developing world.

The resources for dealing with these problems are limited in many countries. Public health education about poisons and infrastructure limiting access and exposure to the most highly toxic chemicals are practically absent in much of the developing world. Access to medical care is often limited for financial, cultural, and geographic reasons. Medical toxicology is frequently not a recognized specialty and patients are evaluated by general physicians with little training—although often with great experience. Diagnostic facilities are few, effective treatment options even more rare. Where antidotes exist, there is rarely enough knowledge or experience to use them effectively.³⁰ Intensive care beds for invasive monitoring and long-term ventilation are scarce. This chapter outlines some of the major poisoning risks and challenges for medical toxicology in the developing world.

POISONING AND THE GLOBAL BURDEN OF DISEASE

The World Health Organization (WHO) has ranked injury, including poisoning, among the top 15 causes of death worldwide for persons aged 5 to 44 years.^{114,174} Recent reanalysis of data from the Global Burden of Disease project estimated that acute and chronic exposure to chemicals caused over 4.9 million deaths and 86 million disability-adjusted life years (DALYs) worldwide in 2004—more than cancer, sexually transmitted diseases, or diabetes.^{135,179} Children younger than 15 years of age bore more than one half of this burden.

Tremendous regional disparities in the health impact of poisoning are apparent. The global mortality burden from poisoning is disproportionately shouldered by lower and middle income countries. Overall, as much as 75% or more of all poisoning related deaths occur in the developing world,⁸¹ and an estimated 95% of children who die each year from acute poisoning live in low-and middle-income countries.¹⁷⁴ Children living in Sub-Saharan Africa are at highest risk, with an estimated annual mortality rate of four children per 100,000 population. This is double the global average and higher than that in any other region.¹⁴²

These figures are striking, yet most likely underestimate the contribution of poisoning to the global burden of disease and disability. Much of the existing data on poisoning epidemiology from lower income countries reflects the experience in larger hospital centers. By contrast, most of the population lives in rural areas, and many patients with poisoning may never reach such facilities for a variety of financial, cultural, or geographic reasons. For example, logistical difficulty with accessing health care facilities was responsible in part for the high mortality from snakebite noted in one community-based study in Nepal.¹⁴⁶ Social or economic barriers often contribute to “healer shopping” within traditional or spiritual systems, with allopathic medical care delayed or avoided in many African countries.^{52,86,128}

Unintentional poisoning risks from occupational, environmental, food, or medication sources may also be poorly recognized in communities, or by health care workers.¹²³ The diagnosis of poisoning may not be suspected if a clear history of exposure is not given, because symptoms can mimic infectious or other processes and few medical centers have ready access to laboratory tests for specific poisons. When poisoning is suspect, many countries lack detailed injury surveillance systems or other standardized reporting mechanisms. The WHO has undertaken several initiatives to improve global poisoning surveillance, including support for poison center (PC) development in under represented regions worldwide, and the international efforts of the IPCS/INTOX programs to harmonize data collection and reporting terminology represent an important step toward this goal. However, the interpretation of PC data as evidence of epidemiologic trends must be approached with some caution (Chap. 136).

COMMON XENOBIOTICS AND PATTERNS OF POISONING

Agents commonly involved in acute poisoning differ substantially between communities, both within and among countries. For example, a comparison of poisoning cases seen at a major public teaching hospital in New York City with two large rural hospitals in Sri Lanka found striking differences in the classes of xenobiotics involved. A total of 70% of the patients in New York City were poisoned with pharmaceuticals, and 90% of patients in the Sri Lankan cohort were poisoned with nonpharmaceuticals, primarily pesticides and botanicals, such as yellow oleander, with a 10 times higher case fatality rate.⁸¹ A study comparing poisoning epidemiology in district (rural) and regional (urban) hospitals in Zimbabwe found that poisoning from pesticides was equally common in both settings, but animal envenomation was seen nearly twice as often at the district facilities compared to regional centers, and poisoning with pharmaceuticals was a problem seen uniquely at the regional hospital.¹⁵⁶

Understanding the local patterns and specific risks for poisoning in particular communities is of critical importance since it provides an evidence base for designing and prioritizing strategies to prevent or limit harm. This section reviews some of the more common xenobiotics implicated in poisoning in developing countries worldwide.

Pesticides

A systematic review suggested that at least 250,000—but more likely 350,000—deaths occur each year from acute pesticide self-poisoning around the world.⁷² The WHO now considers pesticide poisoning to be the single most important means of suicide, accounting for more than one-third of all suicides worldwide.²⁵ Most of these deaths occur in Asia, particularly in China and India.⁷² The annual number of deaths from occupational or unintentional pesticide poisoning is unknown but was estimated 20 years ago at 20,000.⁹⁰

While many classes of pesticides are implicated ([Chap. 113](#)), organic phosphorous (OP) pesticides appear to be responsible for the majority of pesticide-related deaths in the developing world.⁵⁶ Deliberate self-poisoning with OP pesticides puts a high cost on the health care system. In one study examining the experience in Sri Lanka, OP pesticide poisoning was responsible for 943 of 2559 (36%) admissions to a secondary hospital for poisoning.⁶⁰ The case fatality for OP poisoning was 21%, and pesticide poisoned patients occupied 41% of all medical intensive care beds. Similar situations have been reported from across the world.⁵⁶ In all likelihood, such studies underestimate the mortality associated with intentional pesticide ingestion as most are hospital based and do not include patients who die prior to hospital presentation.²

Factors contributing to the high mortality of self-poisoning with pesticides in the developing world include the intrinsic lethality of many pesticides, and health care systems that are poorly prepared to handle such critically ill patients ([Table 137-1](#)). Pesticides are often easily available in highly concentrated preparations in rural communities throughout the developing world. The ease of drinking liquid pesticides is also a factor facilitating massive intentional ingestions, as are inadequate pesticide storage systems.⁹⁹ Outbreaks of unintentional poisoning from contaminated flour or old pesticide containers used to store food still occur in rural areas.⁵⁴ The extraordinarily high human, economic, and social costs of pesticide-related mortality worldwide reinforce the importance of developing simple, economical, and evidence based strategies specifically designed to care for acutely poisoned patients in resource limited environments.^{26,32}

TABLE 137-1. Factors Contributing to High Mortality from Self Poisoning with Pesticides in the Developing World

1. Ease of access to pesticides in rural, agrarian households
2. Poor storage practices
3. Inadequate labeling of lethal pesticide products
4. High potency of pesticides
5. Lack of evidence based practice guidelines appropriate for resource poor areas
6. Lack of clear guidelines
7. Distance from and time to health care facilities and resources available at health care facilities

Envenomation

Envenomation by snakes and other animals represents another significant cause of morbidity and mortality in the developing world. Few countries mandate the reporting of animal bites, making it difficult to estimate global incidence, severity, and outcome. Current data estimates that about 20,000 to 94,000 deaths occur globally each year from snakebite.⁹⁷ The vast majority of deaths and serious envenomations occur in the developing world, with less than 100 snakebite deaths per year estimated to occur in Europe, the United States, Canada, and Australia combined.^{42,97}

Because most rural people in the developing world may first consult traditional healers, hospital based studies of

mortality and morbidity associated with snakebites likely underestimate the scope of the problem.^{42,150} For example, a study of rural Philippine rice farmers found that only 8% of cobra (*Naja philippinensis*) bite victims reached a hospital in the 1980s.¹⁷⁰ However, changes in treatment seeking can occur. Studies over the last decade in Sri Lanka have shown that patients have started going to the hospital rapidly after common krait (*Bungarus caeruleus*) snakebite, bypassing traditional healers.¹⁰³ A study in Ghana found that the incidence of snakebite victims at a district hospital increased significantly after the introduction of a new treatment protocol, possibly reflecting increased confidence in the ability of the health care system to manage these cases.¹⁶⁸

Snakebites are most commonly occupational hazards in the rural tropics. Victims are just as likely to be women as men, reflecting rural farming practices. Working in large plantations and subsistence farms places rural people in frequent contact with venomous snakes. With simultaneous changes in global climate and expansion of human settlements, it is likely that the range of venomous snakes will enlarge to include urban areas and regions previously considered too temperate to support them.^{82,121} Snakebites from members of the Elapidae and Viperidae families are responsible for the majority of deaths worldwide, although several other families are also medically important (Colubridae and Atractaspididae species, in particular; [Chap. 122](#) and Special Considerations: SC8).^{169,172}

The burden of snake envenomation on local resources can be substantial. During the rainy season in Benin, snakebites account for up to 20% of all hospital admissions, with an estimated case fatality rate of 3% to 6%.⁴³ In this region, the annual incidence of snake envenomation ranges from 200 to 100,000 in rural villagers to 1300 to 100,000 in sugar cane plantation workers.⁴³ One study conducted in Nigeria in the late 1970s noted an incidence of 497 per 100,000 and a 12% case fatality (primarily due to envenomation by the carpet viper, *Echis ocellatus*).¹³⁶

After snakebites, the second most common cause of mortality and morbidity from venomous animals is scorpion stings^{88,169} ([Chap. 118](#)). Medically important scorpion species are widely distributed throughout the tropics, being particularly common causes of morbidity in North Africa, Mexico, India, and Brazil.⁴⁴ The total number of medically significant scorpion stings that occurs annually is unknown; a recent review estimated 1.2 million stings, leading to more than 3250 deaths (case fatality 0.27%).⁴⁴ Other venomous insects, such as Arachnida (spiders) and Hymenoptera (bees, ants, and wasps), are rarely sources of significant mortality on a global scale⁸⁸ ([Chap. 118](#)).

Herbal and Traditional Medicines

The use of traditional medicine (TM) to treat or prevent health problems is widespread. The WHO estimates that around 80% of the world's population consults traditional healers regularly.¹⁷⁷ Frequently cited reasons for this preference or reliance on TM include financial considerations, sociocultural preferences, beliefs about the relative safety and efficacy of TM compared to allopathic medicines, and mistrust or relative inaccessibility of doctors.^{86,128} Traditional practitioners still greatly outnumber medical professionals in many regions. For example, in 2004 there was one traditional healer but only 0.04 physicians per 500 inhabitants in Mali.⁷¹

Although TM also encompasses a variety of spiritual, religious, or physical manipulation therapies, it often includes administration of "herbal" remedies (*muti*) either orally or via enema. These are typically prepared using a combination of aqueous plant materials, sometimes mixed with insect or other animal parts, metallic salts, or both. While traditional medicinal preparations have usually been tested by generations of practitioners and the concentrations of active ingredients are generally low, both intentional and unintentional poisonings are common.^{38,94,153,157} In a 2-year retrospective review of acutely poisoned patients from South Africa, TM was the second most common cause of admission (15.8% of cases) and had the highest mortality rate (15.2%), accounting for over half of all deaths in the series.¹⁶⁷ TM was the most common cause of admission (23% of cases) for acute poisoning in another 10-year retrospective review of cases from Zimbabwe, with a 6% mortality rate.⁹⁵

The specific chemical constituents responsible for TM poisoning may vary widely between geographic and cultural areas. Laboratory analysis and ethnopharmacologic surveys in a number of countries have begun to elucidate some of the chemical constituents of commonly prescribed recipes. Interestingly, a review of 41 autopsies in South Africa for which the causative agent was presumed to be an herbal medicine found that cardiac glycosides were present in 44% of cases.¹⁰⁹ Adulterants are also implicated in poisoning from TM formulations. For example, these are common in traditional Ayurvedic medicines (particularly heavy metals⁶³ and corticosteroids⁷⁵) and Asian medicines (particularly synthetic pharmaceuticals and heavy metals³⁶ [Chap. 45](#)). A Taiwanese study of 2609 samples found that 23% were adulterated with pharmaceutical products such as caffeine, NSAIDs, acetaminophen, and diuretics.⁸⁴

Pharmaceuticals

In many lower income countries, pharmaceuticals are relatively uncommon causes of acute poisoning. However, the incidence appears to be rising in conjunction with larger global demographic shifts toward increased urbanization and industrialization. Access to a wider array of medications is relatively greater among urban dwellers than in rural ones, and

more people in urban communities may have the financial means to buy them. In a retrospective review of poisoning cases admitted to urban versus rural health centers in Zimbabwe, poisoning with pharmaceuticals was uniquely seen at the urban facilities, accounting for more than 15% of poisoning cases at regional hospitals surveyed and none of the cases presenting for care at the district level.¹⁵⁶ The relative importance of pharmaceuticals in global poisoning trends is likely to continue over the next decades as the number of therapeutic drugs available for use in lower income countries expands, and more and more societies shift toward a “dual burden of disease” pattern, including chronic illnesses that require long-term drug therapy.^{21,120}

The pharmacopeia available in low-income countries is often more restricted than in higher income countries, and this is reflected in the types of medications implicated in acute poisoning cases. The most common xenobiotics seen in the developing world are those used to treat tropical diseases. For example, self-poisoning with the antimalarial chloroquine (Chap. 59) has been widely reported in Sub-Saharan Africa,^{20,27,116,137} although this medication is now rarely used so the incidence may soon decrease. Intentional and unintentional poisoning with the leprosy drug dapsone, as well as the tuberculosis drug isoniazid (Chap. 58), are also well reported.^{132,158,159,165}

Criminal poisoning of commuters to facilitate robbery is a common problem across South Asia.^{89,117,133} In the 1970s and 1980s, drinks containing extracts of *Datura stramonium* were given to unsuspecting commuters, resulting in anticholinergic poisoning.⁹⁸ Practice has changed recently and benzodiazepines are now more commonly given for this purpose.¹⁰⁸ As many as 300 people are admitted unconscious with this problem to a single university medical unit in Dhaka each year.¹⁰⁸

A more general issue of toxicologic concern is the prevalence of poor-quality medicines in use worldwide. Although data estimating the extent of the problem and its impact on health are limited, recent estimates suggest that more than one-third of all medicines on sale in Southeast Asia and Sub-Saharan Africa are substandard or counterfeit.^{23,118,119} The major problem with these medications is an absence or subtherapeutic concentration of active ingredient, leading to treatment failures and an increase in drug-resistant pathogens where antimicrobials are involved. However, substandard medications may sometimes contain more active ingredient than stated, leading to adverse drug effects,¹⁶¹ or contain harmful adulterants or contaminants.

Epidemic poisonings from such poor quality medicines underscore the dangers of inadequate regulation and oversight of pharmaceutical manufacture and sales. Recent examples include the deaths of more than 120 patients in Karachi from exposure to a batch of isosorbide mononitrate contaminated with pyrimethamine,¹⁵ the hospitalization of more than 50,000 infants in China with melamine poisoning from adulterated formula,⁸⁷ and the numerous epidemics of diethylene glycol poisoning in multiple countries over the past few decades from contaminated glycerine, paracetamol syrups, cough syrups, toothpastes, teething mixtures, and other medications.^{22,79,125,127,140,148}

Household Products and Chemicals

Poisoning with common household products, such as fuels, cleansing products, rat poisons, insecticides, body care products, and cosmetics, is a global problem. This general category of diverse xenobiotics is consistently implicated as a significant source of unintentional childhood poisoning worldwide. The PC movement that began in the 1950s in North America grew out of an increasing recognition of the child health risks associated with exploratory household poison ingestions. Household chemicals are a similarly well recognized risk for unintentional childhood poisoning in Sub-Saharan Africa, accounting for up to 80% of all pediatric admissions for poisoning.^{21,41,45,96,126} Internationally, the specific risks are remarkably consistent, including age younger than 6 years (with toddlers younger than 3 years of age most affected), male sex, low socioeconomic status, and unsafe storage practices in the home.

Among specific household products, hydrocarbon poisoning from unintentional ingestion of kerosene (paraffin) is widely reported as the most common cause of pediatric admissions in low-income countries around the world.^{41,45,96,102,173} Kerosene is a common fuel used to power stoves and lamps in many relatively poor communities. It is pale in color with an appearance similar to water, and it is often purchased or stored in used beverage containers making it easy to misidentify (Chap. 108).⁶² In Sub-Saharan Africa, kerosene poisoning accounts for some 25% to 75% of all poisoning-related hospital visits among children younger than 6 years of age.¹²² Several studies document an increase in poisoning related admissions during the warmer months of the year, when children are more likely to become thirsty and to drink from any beverage container at hand.^{101,102}

Caustics are another group of household products frequently implicated in poisoning in the developing world. The common form of caustic ingested varies between countries. In many countries, alkaline substances are most frequently implicated, whereas in others, such as Taiwan and Morocco, poisoning with hydrochloric or sulfuric acids may be more common.^{3,105,154,180} Acute poisoning carries substantial mortality risk, usually more than 10%. If the acute phase of caustic poisoning is survived, there also is a high rate of delayed complications, primarily esophageal strictures. Delayed complications may require surgical intervention, balloon dilatation of the esophagus (bougienage), or feeding tube placement. These treatments are expensive, require significant hospital resources, and have inherent morbidity and

mortality ([Chap. 106](#)).

As with other categories of poison, patterns of self-harm using domestic products tend to demonstrate regional particularities. For example, in Hong Kong there is significant morbidity reported in association with self-poisoning using common household detergent products such as dettol (4.8% chloroxylonol, pine oil, and isopropyl alcohol) and savlon (cetrimide).^{34,37,39,46} Frequent use of potassium permanganate for self-harm has also been reported from Hong Kong.^{129,181} Fatal poisoning with hair dye (paraphenylenediamine) is known in the Middle East and North Africa.^{29,61,80,151} Barium sulfide, arsenic sulfide, and calcium oxide are contained in hair removal preparations¹⁴⁶; poisoning from ingestion of these preparations has been reported from India and Iran.⁴ Rubigine is a domestic cleansing product containing hydrofluoric acid and ammonium difluoride that is used for self-harm in the Caribbean,⁸⁵ while ingestion of sodium hydroxide is common in Malaysia.¹⁹

Plants

Poisonous plants have been used therapeutically to induce abortion, for recreational intoxication, in homicidal acts, and for self-harm throughout human history ([Chap. 121](#)). This section briefly mentions select toxic plants that are most commonly used in self-poisoning, or that have caused epidemic poisoning in the developing world.

Self-poisoning with seeds of two plants containing cardioactive steroids are important clinical problems in Asia. Yellow oleander (*Thevetia peruviana*) kills hundreds of people each year in Sri Lanka and India^{28,57} ([Chap. 65](#)). Sea mango (*Cerbera manghas*) has killed hundreds of people in Kerala, India,⁶⁸ and is a focal problem in eastern Sri Lanka.⁵⁸ Oduvan (*Cleistanthus collinus*) leaf contains the glycosides cleistanthin A and B, which produce severe hypokalemia and cardiac dysrhythmias.¹³ Self-poisoning has killed hundreds of people in Tamil Nadu, India.^{12,155} The superb lily (*Gloriosa superba*) contains colchicine alkaloids and has also been used for self harm in South Asia^{5,9,111} ([Chap. 36](#)).

Ackee tree fruit (*Blighia sapida*), which contains hypoglycin when unripe, is widely consumed as a food source. Epidemics of fatal poisoning with unripe Ackee fruit have occurred throughout the Caribbean and in Africa.^{64,92,110,112} Poisoning by castor beans (*Ricinus communis*) or other lectin containing plants such as *Jatropha* spp (African purging nut) is well reported from Africa and South Asia^{1,65,78,93} ([Chap. 121](#)).

Numerous plant species contain atropine like alkaloids, causing an anticholinergic syndrome when ingested. Reports of intentional ingestion of *Datura* species have been reported from Africa, Asia, and Latin America.^{78,143,152} Most commonly, the seeds are ingested as a recreational drug for their hallucinatory effects,^{67,138} or as part of traditional medical preparations.³⁵

Occupational and Environmental Sources

Poisoning from occupational and environmental sources is a significant global health problem, with disproportionate effects on persons living in lower income communities around the world. Exposure to “traditional” environmental health hazards, such as indoor air pollution from the combustion of solid fuels, and naturally occurring contaminants in groundwater, soil, and food, is still a major cause of morbidity and mortality in much of the world. Around 50% of the world’s people rely on solid fuels such as coal, dung, wood, or crop residues for cooking and heating.³¹ Resultant indoor air pollution was estimated to cause 1,965,000 deaths and 41,009,000 DALYs from lower respiratory tract infections, cancers, and COPD in 2004.¹⁷⁸ In Bangladesh, arsenic contaminated groundwater contributed to 9100 deaths and 125,000 DALYs in 2001.¹⁰⁷ Dental and skeletal fluorosis from excessive fluoride in drinking water is endemic in at least 17 countries worldwide.⁶⁶

Increasingly, modern environmental health hazards (MEHHs) also play a large role in global poisoning risks.^{49,124} MEHHs include outdoor air pollution from automobiles and factories, soil and water contamination by plastics, heavy metals, pesticides and other industrial chemicals and wastes, radiation hazards, land degradation, and climate change produced by rapid urbanization and industrial development in the absence of strong regulatory controls.⁴⁹ These are important sources of both occupational and environmental exposure to a wide range of toxins with acute and chronic health effects. Inadequate safeguards to control the selection, sale, and application of pesticides in parts of Africa and Asia are linked to pesticide poisoning both as an occupational hazard^{53,91} and from residues left on food.^{11,48,123} Occupational lead poisoning has largely been controlled in developed countries through improved working conditions and occupational health screens, but remains an enormous problem in developing countries where occupational and environmental health protection measures are often underdeveloped or practically nonexistent.^{164,171}

Industrial factories are often placed in urban areas, or the areas around factories are rapidly urbanized, placing large numbers of people at risk not only from pollution but from industrial errors as well. The 1984 Bhopal tragedy in which a Union Carbide pesticide plant malfunctioned, releasing isocyanate gas into the surrounding community and causing an estimated 3787 deaths and 558,125 injuries, is emblematic of such disasters.^{14,145}

Several international agreements on chemical safety provide legal frameworks to mitigate the human and environmental impact of global industrialization; however, the actual implementation of regulatory controls has lagged behind the expansion of toxic exposures. For example, at the level governance a total of 39 Sub-Saharan African countries have ratified the Rotterdam Convention on chemical safety. Yet industrial pollution is now becoming so highly concentrated in growing urban areas that the continent's pollution intensity (pollution generated per unit of production output) is now rated among the world's highest, attesting to significant regional difficulties in enforcing such regulations.¹⁶⁶

The predominance of informal sector activity in agricultural and industrial work in lower income countries poses serious regulatory challenges. Fumes and dusts from small-scale domestic businesses involved in smelting, battery recycling or manufacture, welding, pottery, ceramic production, and artisanal mining are common sources of exposure to lead and other heavy metals in developing countries, and put not only workers but whole communities at risk.¹⁶⁴ More recently, unregulated electronic waste (e-waste) recycling, in which salable metals are reclaimed from old electronics by burning, has emerged as a significant human and environmental health hazard in parts of China, West Africa, and India.^{7,104,160} Workers are often aware of the health risks, yet economic hardship and lack of alternative employment make them unwilling or unable to change.

Easy access to industrial chemicals from inadequate regulation of packaging and sales may also facilitate their use for intentional self-harm. For example, formic and acetic acids are used in the manufacture of rubber, and case series are reported from areas surrounding rubber factories in India and Sri Lanka.¹³⁹ Copper sulfate is widely used for self-poisoning in parts of South Asia, and carries a high mortality rate due to direct damage to the gastrointestinal tract, hepatorenal failure, and hemolysis^{6,144} (Chap. 95). Cyanide has become a commonly used method in Korea over the last 20 years¹⁰⁶ (Chap. 126).

REDUCING THE GLOBAL IMPACT OF POISONING

Regulatory science and the coordinated actions of agencies and programs across multiple sectors play a vital role in preventing or reducing the impact of poisoning in society. Within the health sector, significant inter-and intraregional disparities in access to health care have a major impact on poisoning outcomes. Lack of human resources to provide acute care is an enormous problem in many parts of the developing world. In Mozambique, there is only one trained medical doctor for every 33,000 individuals, compared with 1 in 390 persons in the United States. Tanzania has a nurse to population ratio of 1:2700 individuals compared with 1:107 individuals in the United States. Policies and programs encouraging sustainable and equitable health workforce development are needed foundation to improve health care access globally.⁵⁰

Beyond rectifying the raw numbers deficit, clinical training programs in many low and middle income countries must be upgraded to promote broad exposure and specialist development in clinical toxicology and acute care. Increasing local and international commitment to the growth of emergency medicine in low-and middle-income countries promises to support the dissemination of scientific knowledge and improve provider competence in advanced resuscitation techniques.^{8,16,70} Significant gaps in infrastructure and resources to provide basic critical care interventions and meet WHO minimum standards for essential emergency supplies must also be addressed.^{17,18,83}

In addition to global disparities in acute care infrastructure generally, access to antidotes for specific poisons is either lacking or inadequate in much of the world.^{10,131,176} Poor antidote availability is not unique to the developing world,⁵¹ and many antidotes may be considered either adjunctive or unnecessary therapies. However, in certain cases they can significantly reduce the need for other medical interventions, and this may be particularly important in rural or underdeveloped areas where critical care facilities are not readily available.¹³⁴ For example, the most important challenge to improving the treatment of patients with snakebite worldwide is poor antivenom availability, particularly in rural areas where it is most needed to reduce critical delays in administration.^{162,163} Currently, many available antivenoms are prohibitively expensive, ineffective, or have a high rate of adverse reactions. Equally important, some antivenoms must be refrigerated, making storage impractical in many rural areas where the need is most acute. Critical evaluation of existing antivenoms and development of new products are thus desperately needed^{24,30,76,77,105,162,163,172,175} (Special Considerations: SC8).

Where antidotes are available, knowledge and experience to know how to use them safely and effectively is often lacking.³² Input from experts in medical toxicology improves outcomes, reduces hospital stays and health care costs associated with acute poisoning,^{33,47,69} but practitioners in many parts of the world have limited or no access to consultation with such specialists. The mission of the International Union of Toxicology is to foster international scientific cooperation, ensure the development of toxicologists, and promote the dissemination of knowledge in toxicology worldwide.⁵⁵ Through the collaborative efforts of this and other regional professional societies, an increasing number of online, regional, and international forums now offer educational and professional development opportunities in clinical toxicology around the globe. More work is needed to promote awareness and the growth of the specialty in all regions.

Improving health care access and health system preparedness is only one aspect of the coordinated, multilevel, national, and international public health responses needed to reduce the global impact of poisoning. Prevention and risk reduction efforts must involve locally appropriate community level education and awareness raising, strong governance to support the design, implementation, and monitoring of regulatory controls, and the involvement of multiple stakeholders and sectors including water, waste management, energy, agriculture, transportation, industry, and civil society. Effective legislative frameworks developed in countries with more advanced public health infrastructure have been successfully disseminated in some cases. For example, between 2000 and 2004 the proportion of people with blood lead concentrations above 10 µg/dL globally decreased from 20% to 14%, largely due to the widespread phase out of leaded gasoline.¹³⁵ Other strategies, such as pharmaceutical and food safety regulations enacted through the US Food and Drug Administration, have influenced “duplicative legislation” in other countries but continue to pose significant implementation challenges in low and middle income countries that lack the necessary financing, human resources, and infrastructure to enforce them well.¹³⁰

Many public health measures with proven efficacy, such as routine lead testing during childhood, the regulation of vehicle emissions, the detection of carbon monoxide, and the incorporation of childproof containers may seem prohibitively resource intensive in many parts of the world. The development of new, low-cost technologies such as solar heating and electrical sources, chemical assays and residue detectors, and electronic devices to identify and track pharmaceuticals hold some promise to reduce global risks for unintentional poisoning. More research is needed to propose and evaluate the effectiveness, acceptability, and sustainability of new and proven poison prevention techniques in resource-limited environments.

Recognizing that self-harm from pesticide ingestion is responsible for a majority of acute poisoning deaths worldwide, public health interventions specifically designed to limit access are an important goal. A minimum pesticide list, based on the WHO essential xenobiotic list initiative, has been proposed.⁵⁹ Such a list would provide policy makers and farmers with unbiased information about relative risks. However, voluntary initiatives such as international policy statements and industry sponsored programs often suffer from a lack of resources, a shortage of political will, and nonexistent enforcement mechanisms.^{100,115} A dramatic illustration of an effective national program to reduce pesticide poisoning risks is the ban of all WHO high-risk OP insecticides and the organic chlorine endosulfan in Sri Lanka, which effectively arrested a previously exponential increase in the incidence of pesticide poisoning and halved the national suicide rate between 1995 and 2005.⁷³ This program is estimated to have saved more than 20,000 lives in 10 years.⁷³

Ironically, some programs to remove the most environmentally persistent and toxic chemicals from use have inadvertently replaced them with agents highly toxic to humans. The replacement of persistent organic chlorine compounds with carbamates in malaria control programs is an example. The opposite effect has also occurred, for example, by replacing OP insecticides with pyrethroids to reduce human toxicity.¹⁰⁰ Coordinated pesticide harm reduction strategies should take into account concerns regarding both environmental and human toxicity, and anticipate which xenobiotics will enter into use as replacements as specific chemicals are phased out.¹⁴¹ A strategy based on industrial hygiene models of a hierarchy of controls has been proposed by several authors^{115,141}(Table 137–2).

TABLE 137–2. Hierarchical Strategies to Reduce Pesticide Poisoning Mortality in the Developing World¹⁰⁸

E	Most	Eliminate the most highly toxic pesticides
F		Substitute with less toxic, equally effective alternatives
F		Reduce use through improved equipment
I		Isolate people from the hazard
C		Label products and train applicators in safe handling practices
A		Promote use of personal protection equipment
C		
Y	Least	Institute administrative controls

SUMMARY

- Poisoning is a common worldwide. Fatal poisoning is disproportionately concentrated in lower and middle income countries, where public health systems and acute care resources to detect, manage, prevent, and collect data on poisoning are often less well developed.
- Global poisoning estimates are mostly derived from health care sources in a minority of developing world countries; current data may underrepresent the true burden and distribution of injuries from poisoning.
- Efforts to develop international poisoning surveillance systems and establish harmonized definitions of poisoning cases will help generate a more complete picture to inform local, national, and international policies and interventions.
- Pesticides are the most important cause of death from acute poisoning worldwide, with a majority of cases attributable

to acts of deliberate self harm.

- Improving access to health care and health system preparedness to provide acute care is essential to reduce global disparities in poisoning outcomes.
- Randomized controlled trials and cost effectiveness research are needed to critically evaluate the utility of specific public health and treatment interventions in resource limited settings.

138 PRINCIPLES OF EPIDEMIOLOGY AND RESEARCH DESIGN

Alex F. Manini and Kevin C. Osterhoudt

Advances in medical toxicology are achieved through the scientific method using observations, derived from cases of poisoning and nonpoisoning due to xenobiotic exposures, to generate hypotheses. Subsequent research questions are analyzed with epidemiological investigation, and preliminary studies are examined with methodological scrutiny. Initial analytical techniques are improved, and confirmatory studies are performed. Ultimately, models relating cause to effect are formulated.

To optimize patient care, it is useful to grade the quality of available scientific evidence used to justify treatment recommendations. Decisions about how strongly to recommend a medical action will be based on the careful consideration of the risks of leaving a patient untreated, the potential benefits and harms of treatment, the quality of the guiding evidence, a balanced view of resource utilization, and the values of the person to be treated. The Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Working Group has provided a framework for assessing and communicating levels of scientific evidence ([Table 138–1](#)).²² An understanding of basic principles of research design and epidemiology is required to interpret published studies and to lay the groundwork for future investigation in toxicology.

TABLE 138–1. GRADE System for Evaluating Clinical Recommendations

<i>Strength of Recommendation</i>	<i>Quality of Evidence</i>
Strong	High
Weak	Moderate
	Low or very low
<i>Strength/Quality Aggregate</i>	<i>Implications</i>
Strong/high	<ul style="list-style-type: none"> • Recommendation can apply to most patients in most circumstances • Further research is unlikely to change our confidence in the estimate of effect
Strong/moderate	<ul style="list-style-type: none"> • Recommendation can apply to most patients in most circumstances • Further research (if performed) is likely to have an important impact on our confidence in the estimate of effect and may change the estimate
Strong/low	<ul style="list-style-type: none"> • Recommendation may change when higher quality evidence becomes available • Further research (if performed) is likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate
Weak/high	<ul style="list-style-type: none"> • The best action may differ depending on circumstances or patients or societal values • Further research is unlikely to change our confidence in the estimate of effect
Weak/moderate	<ul style="list-style-type: none"> • Other alternatives may be equally reasonable • Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate
Weak/low	<ul style="list-style-type: none"> • Other alternatives may be equally reasonable • Any estimate of effect, for at least one critical outcome, is very uncertain

EPIDEMIOLOGIC TECHNIQUES AVAILABLE TO INVESTIGATE CLINICAL PROBLEMS

Table 138–2 lists the different study formats discussed below.

TABLE 138–2. Epidemiologic Study Designs: Types, Measurements, and Advantages

<i>Study Design^a</i>	<i>Main Measurement</i>	<i>Advantages</i>
Clinical trial	Efficacy	Gold standard for drug development
Noninferiority trial	Safety	Noninferior drugs may be better tolerated, cheaper, or easier to use
Cohort	Incidence, Risk Factors	Provides more robust evidence of association Reduced bias in exposure data Can study many outcomes simultaneously Allows direct calculation of incidence Allows direct calculation of relative risk
Case control	Association	Smaller sample required when outcome is rare Reduced bias in outcome data Can study many exposures simultaneously Allows estimation of relative risk May obviate need for long follow-up period
Analysis of secular trends	Population Trends	Examine trends in disease events over time Study across different geographic locations Can correlate them with trends in putative exposures
Cross-sectional	Prevalence	Uncover relationships for future study Highly feasible
Case series	Descriptive	Characterize new syndromes or exposures
Case report	Descriptive	Identify signals for hypothesis generation

^aStudy designs are listed in descending order from the design that offers the best epidemiologic evidence for association to that which offers the least.

Observational Design: Descriptive

A staggering array of xenobiotics are able to injure people, necessitating reliance of toxicologists on good descriptive data regarding toxic outcomes. Through 2011, the National Poison Data System (NPDS) of the American Association of Poison Control Centers (AAPCC) has amassed a database of more than 50 million human exposures ([Chap. 136](#)). Descriptive case reporting serves a valuable purpose in describing the characteristics of a medical condition or procedure and remains a fundamental tool of epidemiological investigation. A case report is a clinical description of a single patient or procedure in a unique context. Case reports are most useful for hypothesis generation. However, single case reports are not always generalizable, as the reported situation may be atypical. A number of case reports can be grouped on the basis of similarities into a case series. Case series can be used to characterize an illness or syndrome, but without a control group they are severely limited in proving cause and effect. In 1966, a case series of two patients with acute liver necrosis following overdose of acetaminophen (APAP)¹² was accompanied by a case report of liver damage and impaired glucose tolerance after APAP overdose,⁴⁰ which led to further study and the eventual creation of the Rumack-Matthew nomogram ([Chap. 35](#)). Similarly, a 1979 case report of “hypertension and cerebral hemorrhage after trimolets ingestion”²⁴ led to subsequent animal studies, experimental human studies, and epidemiologic studies culminating in the decision by the US

Food and Drug administration to remove phenylpropanolamine from nonprescription cold remedies and appetite suppressants ([Chap. 42](#)). The important role for descriptive data in guiding clinical research, focusing educational efforts, and formulating public policy are often underappreciated.

Cross-sectional studies assess a population for the presence or absence of an exposure and condition simultaneously. Such data often provide estimates of prevalence—the fraction of individuals in a population sharing a characteristic or condition at a point in time. These studies are particularly helpful in public health planning and have been extremely useful in monitoring common environmental exposures, such as childhood lead poisoning, or population-wide drug use, such as occurs with tobacco, marijuana, and alcohol. The US National Health and Nutrition Examination Survey demonstrated that the percentage of children with blood lead concentration greater than 10 $\mu\text{g/dL}$ decreased from 88.2% to 4.4% between 1976 and 1991, with the highest rates of plumbism among African American, low-income, or urban children.⁵

An analysis of secular trend is a study type that compares changes in illness over time or geography to changes in risk factors (ecological). These analyses often lend circumstantial support to a hypothesis; however, because of the ecologic nature of their design, individual data on risk factors are not available to allow exclusion of alternative hypotheses also consistent with the data. A prime example of an analysis of secular trends is the finding that reports of Reye syndrome declined between 1980 and 1985, coincident with a fall in sales of, or physician recommendations of, children's salicylate products.⁴ This investigation suggested an etiologic role of salicylate in the development of Reye syndrome but could not exclude alternative hypotheses such as a change in viral epidemic patterns.

Observational Design: Analytical

Hypotheses that are generated by theoretical reasoning or anecdotal association require analytical testing. Case-control studies and cohort studies are analytical techniques that use observational data, and each technique has its own advantages and disadvantages ([Table 138–2](#)). Case-control studies compare affected, treated, or diseased patients (cases) to nonaffected patients (controls) and evaluate for a difference in prior risk factors or exposures ([Fig. 138–1A](#)). Because participants are recruited into the study based on prior presence or absence of a particular outcome, case-control studies are always retrospective in nature. They are especially useful when the outcome being studied is rare, and they enable the investigation of any number of potential etiologies for a single disease.

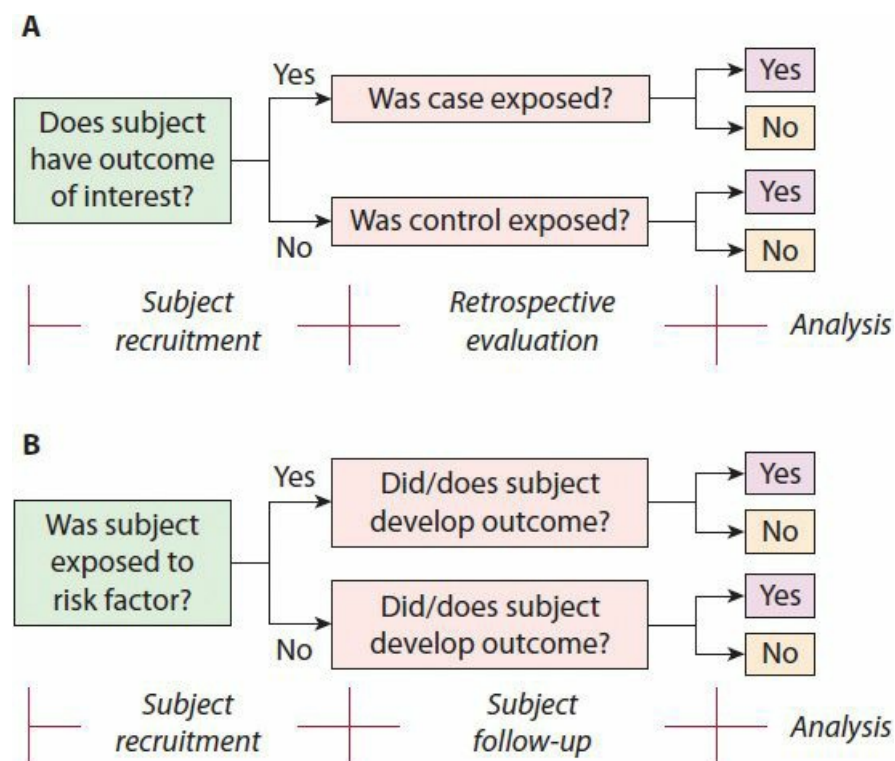

FIGURE 138–1. (A) Schematic representation of the case-control study design. Participants with an outcome or condition of interest are selected, along with control participants, and then are evaluated for previous exposure to a risk factor of interest. (B) Schematic representation of the cohort study design. Participants are recruited based on the presence or absence of a risk factor or exposure, then followed to see if they develop an outcome.

The hypothesis, derived from multiple case reports and case series, that phenylpropanolamine might increase risk for hemorrhagic stroke was well suited to case-control study. Exposure to ingested phenylpropanolamine, as an ingredient in cold remedies and appetite suppressants, was common; but hemorrhagic stroke is rare among children and young adults. Other putative risk factors such as tobacco use, hypertension history, family history, cocaine use, and contraceptive use were identifiable and could be studied simultaneously. In a case-control analysis of 702 participants with hemorrhagic

stroke and 1376 controls, the use of appetite-suppressant doses of phenylpropanolamine were found to be independently associated with the occurrence of hemorrhagic stroke.²³

Cohort studies compare patients with certain risk factors or exposures to those patients without the exposure, and then follow these cohorts to see which participants develop the outcome of interest (Fig. 138–1B). In this respect, they allow the comparison of incidence (the number of new outcomes occurring within a population initially free of disease over a period of time) between populations who share an exposure and populations who do not. They may be retrospective or prospective and enable the study of any number of outcomes from a single exposure. They are particularly well suited to investigations in which the outcome of interest is relatively common. In circumstances when an outcome of interest is very uncommon, such as the case with stroke after phenylpropanolamine use, the large number of study participants required might make a cohort study impractical. A cohort of 981 APAP overdose participants was used retrospectively to investigate whether administration of activated charcoal might be beneficial therapy for APAP poisoning.⁸ Participants were separated on the basis of whether or not they were treated with activated charcoal and were subsequently followed to see if they developed concentrations deemed toxic by the Rumack-Matthew nomogram. Perhaps the most famous cohort study was the Framingham Heart Study in which 5209 residents of Framingham, MA, aged 30 to 62 years, were followed for over 50 years. This study provided a useful tool for studying the incidence of lung cancer, stroke, and cardiovascular disease in those exposed to cigarette smoke and other hazardous xenobiotics.¹³

Experimental Design

Experimental studies are those in which the treatment, risk factor, or exposure of interest can be controlled by the investigator to study differences in outcome between the groups (Fig. 138–2). The prototype is the randomized, blinded, controlled clinical trial. Among epidemiologic study types, these provide the most convincing demonstration of causality. Clinical trials are used to measure the efficacy (the treatment effect within a controlled experimental setting) of treatment regimens and to draw inferences about the effectiveness of a treatment applied to the general population. Sometimes a trial can be designed to study drug treatments that are hampered by nonresponders to therapy, expensive drugs, or poorly tolerated regimens. Such trials are termed noninferiority trials, and operate on the null hypothesis that the new (study) drug is worse than the control (standard) drug. Thus, finding a difference between groups in a noninferiority trial means that the alternative hypothesis can be accepted that the new drug is not worse than the standard treatment.

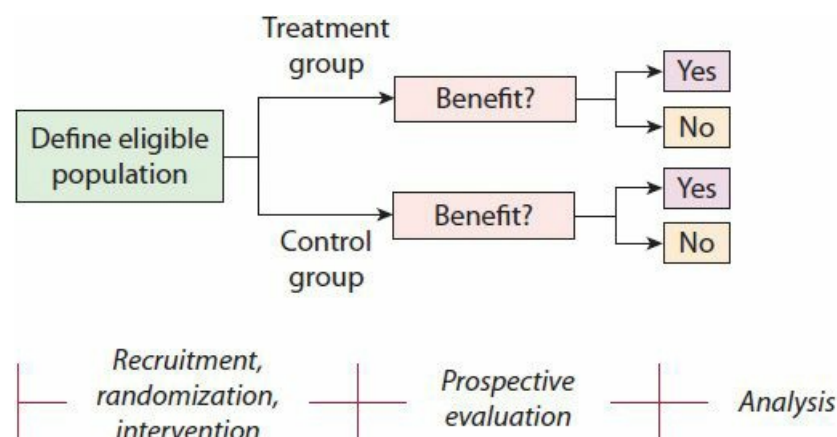

FIGURE 138–2. Schematic representation of the design of a randomized clinical trial.

Unfortunately, interventional studies are the most complex to perform, and several questions must be addressed by investigators before performing a clinical trial (Table 138–3). Human clinical trials have been especially difficult to apply to the practice of toxicology. Table 138–4 lists characteristics of poisoned patients, which hamper attempts at clinical trials. Volunteer studies, using nontoxic xenobiotics or nontoxic doses of toxic xenobiotics, are often used to circumvent many of the problems in controlling human poisoning studies; but it is typically difficult to apply results from these studies to the actual context of toxic overdoses. In an experimental, human volunteer study, activated charcoal reduced absorption of ampicillin by 57%.³⁹ Taken out of this artificial setting, a trial of single-dose oral activated charcoal was unable to prove benefit to outcome among 1479 heterogeneous participants presenting to an emergency department (ED) for possible poisoning.²⁹ Neither study was able to answer whether activated charcoal reduces morbidity from ingestion of dangerous xenobiotics if given while the xenobiotic is still in the stomach and amenable to adsorption.

TABLE 138–3. Considerations in Designing a Clinical Trial

What is the question of interest?
 What is the target patient population?
 How will the safety of subjects be assured?

What is a suitable control group?
How will outcomes be measured?
What difference in outcomes between groups is considered important?
What is the analysis plan?
How many subjects will be required?
How will randomization and blinding be achieved and maintained?
How long a follow-up period will be required?
How will loss of study subjects be addressed?
How will treatment compliance be evaluated?

TABLE 138–4. Difficulties in Utilizing Clinical Trials to Study Human Poisoning

It is unethical to intentionally “poison” subjects.
Poisoned patients represent a broad spectrum of demographic patterns.
A wide variety of xenobiotics exist.
Exposures to any single xenobiotic are usually limited.
A limited number of poisoned patients are available at any one study site.
Uncertainty often exists as to type, quantity, and timing of most xenobiotic exposures.
Poisoning typically results in a relatively short course of illness.

As toxicologists strive to find evidence for, or against, the traditions of clinical practice, several important clinical trials have been published. Among them are many important examples and lessons in epidemiologic study design. One trial attempted to evaluate whether or not corticosteroids might be beneficial in preventing esophageal strictures secondary to circumferential caustic injury of the esophagus.³ Because of the inherent difficulty in recruiting eligible patients from a single institution, only a small sample of 60 patients with esophageal injury were recruited over an 18-year period. Another study randomized hyperbaric oxygen therapy versus sham (placebo) therapy, among 152 victims of carbon monoxide poisoning, to investigate its effect on the development of neurocognitive injury.⁴² Certain concerns with the methodology and analyses of clinical studies are examined later in this chapter to illustrate epidemiologic concepts, and must be carefully considered when trying to apply the results of any clinical trial into the patient care setting.

MEASURES USED TO QUANTIFY THE STRENGTH OF AN EPIDEMIOLOGIC ASSOCIATION

The objective of analytical studies is to define and quantify the degree of statistical dependence between an exposure and an outcome. Such associations are ideally represented by the relative risk of developing an outcome if exposed in comparison to being unexposed. Thus, the relative risk can be defined as the incidence of outcome in exposed individuals compared to the incidence of outcome in unexposed individuals. The relative risk can be calculated directly from cohort or interventional studies. However, in a case-control study, an investigator chooses the numbers of cases and controls to be studied, so true incidence data are not obtained. In case-control studies an odds ratio can be calculated, and the odds ratio will provide an estimate for relative risk in situations in which the outcome is rare, such as when the outcome occurs in fewer than 10% of exposed individuals. **Figure 138–3** demonstrates the calculation of relative risk or odds ratio from analytic studies.

		Outcome	
		Yes	No
Exposure	Yes	a	b
	No	c	d

Cohort study
Relative risk = $\frac{a}{a+b} \div \frac{c}{c+d}$

Case-control study
Odds ratio = ad/bc

FIGURE 138–3. Use of a 2×2 table to calculate or estimate relative risk from analytic studies. In cohort studies, study participants are selected on the basis of exposure. In case-control studies, participants are selected on the basis of outcome. The letters a, b, c, and d represent the number of participants either exposed or unexposed to a “risk factor” or treatment, with or without the outcome of interest. The odds hazard ratios estimate the relative risk if the outcome of interest is rare.

A relative risk of 1.0 signifies that an outcome is equally likely to occur whether an individual either is exposed or is not exposed and implies that no association exists between the exposure and the outcome. A relative risk approaching 0 suggests that an exposure is a marker of protection regarding the outcome, and a relative risk approaching infinity suggests the exposure predicts a tendency toward the outcome. Among men and women using phenylpropanolamine appetite suppressants, the odds ratio for development of hemorrhagic stroke was 15.9 which suggests a strong association.²³

MEASURES USED TO QUANTIFY THE SIGNIFICANCE OF AN EPIDEMIOLOGIC ASSOCIATION

One of the essential features of research in medical toxicology is integration of the available data, whether clinical or experimental, into logical assumptions about how the overall system functions. Systems that are studied in medical toxicology research typically involve either elucidation of how a toxic insult influences normal physiology, or the mechanism and degree to which an antidote mitigates toxicity. Prior to undertaking a study, medical toxicology investigators may have no way of knowing whether their hypothesis is correct or applies at all. Thus, predictions made based on a priori hypotheses may be tested by performing experiments or by sampling observed data in an organized fashion. If the results are consistent with the predictions, then the hypothesis is retained. If they are not, then the prior hypothesis is rejected and a new hypothesis is formulated. This process is the basis of the scientific method and is also known as hypothesis testing.

Determination of whether the observed data in a toxicology investigation allow us to retain or refute our a priori hypothesis depends on our ability to gauge the certainty that the data were arrived at by chance. When observing a set of data, investigators can never be 100% certain that what they observed actually happened; it is possible that confounding factors biased what was observed, and it is possible that the observation was made simply by chance. To deal with this problem of interpretation, researchers use statistical methods to evaluate whether their data were arrived at by chance. The presence of an association between two factors in any given study has a number of possible explanations (Table 138–5).

TABLE 138–5. Types of Associations Between Exposures and Outcomes That May Be Found with a Clinical Study

No association	The outcome is independent of exposure.
Artificial association	
Chance	The association demonstrated by the study resulted from random error.
Bias	Systematic error in the study led to the noted association.
Indirect association	The association is real, but not truly cause and effect (confounding).
Causal association	The outcome is dependent on the exposure.

To differentiate between differences due to chance and potentially real differences between comparison groups,

researchers can use a philosophical trick known as the null hypothesis. The null hypothesis involves beginning experiments with the assumption that there is no difference between groups being compared. Thus, any significant deviation from observed and expected results under the null hypothesis allows the investigator to reject the null hypothesis and adopt the alternative hypothesis. The alternative hypothesis to the null is that the groups being compared are significantly different from one another (ie, not the same).

To begin, one must assign a probability percentage or P value to the likelihood that their observed results are really the case assuming the null hypothesis to be true. With some exceptions, the standard P value deemed to represent ability to reject the null hypothesis has historically been set to 5% (or $P < .05$) in medical toxicology epidemiologic science. This value is also termed the alpha (α), the significance level, the type 1 error, and can also be thought of in layman terms as the chance of falsely finding a difference between groups when one does not exist.

Because analytic studies involve only a sample of the total population, they contain two types of inherent error. Type 1 error, also referred to as an alpha (α) error, is the likelihood that an investigator may conclude that an association exists when none truly does. Type 2 error, or a beta (β) error, is the possibility that an investigator will be unable to find an association when one is really present. The most commonly reported measures of type 1 error in published toxicology studies are the P value and the confidence interval (CI). Statistical significance has customarily, but not necessarily, been defined as having less than a one in 20 chance of conducting a false-positive study. Therefore, a type 1 error of less than 5%, which corresponds to a P value of less than 0.05, is usually deemed “statistically significant.” In some cases investigators must use a significance level (P value) even lower than 0.05 when testing multiple hypotheses at once, for example, in genetic marker studies examining multiple genes across an entire genome. Such a correction is termed the Bonferroni correction, and is applied as the P value divided by the number of variables being tested at once: $P = (\text{significance level}) / (\# \text{ concurrent variables})$.³⁷ The result is a smaller (ie, more stringent) corrected significance level for studies that test multiple hypotheses at once. For example, if a study protocol uses a genetic “chip” assay to evaluate 50 markers at once for an association with a predetermined disease in a population, the Bonferroni correction would require significance at $(0.05)/(50) = 0.001$ in order to deem any association to be statistically significant.

Perhaps a more informative description of the significance of an association is provided through the CI. The CI not only provides a test of statistical significance, it also offers information pertaining to the degree (and possible range) of differences observed. In an unbiased study, the 95% CI provides a range between which, if the study could be repeated an infinite number of times, the observed point estimate would fall between the CI 95% of the time. For example, one study reported that no toddlers ingesting one or two calcium channel blocker tablets became seriously ill, but a subsequent analysis of the CI around this small set of data demonstrated that the true incidence could be as high as 18%.³² A CI around a relative risk or odds ratio is not statistically significant if it includes 1.0, and the narrower the CI the more precise the estimate of the magnitude of effect.

The likelihood that a study will find a difference if one truly exists is termed statistical power and relates to the likelihood of a false-negative study (type 2 error). Power is usually artificially set by an investigator before a study is performed and is typically set at 80% or 90% to practically limit the number of study participants needed. [Table 138–6](#) lists considerations applicable to choice of sample size. The sample size of a study is determined by the frequency of the exposure and outcome within the study population, the strength of association deemed clinically relevant, and the amount of error deemed acceptable in the study. Because power is often set relatively low, it is difficult to state that an association does not exist. It is more appropriate to state that a study was unable to reject the null hypothesis to find an association.

TABLE 138–6. Considerations in Choice of Sample Size

	<i>Sample Size</i>	
	<i>Large</i>	<i>Small</i>
Pros	<ul style="list-style-type: none"> • Able to detect associations of small magnitude • Less susceptible to some biases • More robust analysis 	<ul style="list-style-type: none"> • Less work • Less cost
Cons	<ul style="list-style-type: none"> • More work • More cost 	<ul style="list-style-type: none"> • Might not detect associations of small magnitude • More susceptible to biases associated with patient differences

The finding of a low P value indicates a statistically high level of confidence that a difference between study groups exists but offers no indication that the difference is clinically important. The interpretation of statistical versus clinical significance is often facilitated through calculation of CIs. Small actual differences between two groups can become

statistically significant if large numbers of participants are studied. Likewise, impressive associations of cause and effect can seem trivial if few participants are in a study. The clinical significance of an association is left to the judgment of the individual interpreting a study. Ideally, a working definition of clinical significance is developed before a study is performed.

METHODOLOGIC PROBLEMS FOUND WITHIN CLINICAL STUDIES

The calculation of a P value or CI does nothing to assess the adequacy of study design. These measures are used to quantify the influence of random error, or chance, on research findings. Clinical research involving patients is particularly susceptible to bias, which can be defined as systematic error in the collection or interpretation of data. Because such error can lead to an inappropriate estimate of the association between an exposure and an outcome, careful evaluation of potential biases affecting a clinical study is of paramount importance.

Selection bias refers to error introduced into a study by the manner in which participants are selected for inclusion in the study. This type of bias is most problematic for retrospective studies in which exposures and outcomes have both occurred at the time of participant recruitment. Selection bias may be introduced into a prospective clinical study if the study fails to enroll potential participants, or if potential participants refuse to participate, on a systematic basis. Selection bias may even influence the results of clinical trials. In a 1995 trial that found no difference in outcome between acutely poisoned patients treated with gastric emptying and patients from whom gastric emptying was withheld, all patients presenting to the ED after acute overdose were enrolled.³⁵ Because most patients with poisoning exposure are likely to do well with minimal support, selection of patients on this basis might be expected to bias this study to find no effect. Reasoning suggests that the patients most likely to benefit from gastric emptying are those with life-threatening toxic ingestion presenting within the first hour after overdose. Indeed, subgroup review of the results of this paper suggests clinical benefit within this group of patients, but without conclusive power.

Information bias refers to error introduced into a study as a result of systematic differences in the quality of data obtained between exposed and unexposed groups, or between those with and without the outcome of interest. Several distinct types of information bias may exist. Affected and nonaffected individuals may have differential memories regarding exposures, so recall bias is a concern in retrospective studies. The potential for recall bias may be cited as criticism of retrospective case-control studies of the association between phenylpropanolamine and hemorrhagic stroke, in which patients and families were asked to recollect their phenylpropanolamine use history. Stroke victims and their families might be more vigorous in their recall of exposures than control participants. Similarly, interviewer bias may occur if study personnel differ in how they solicit, record, or interpret information as a result of knowledge of participant status regarding exposures or outcomes.

Prospective studies may be troubled by loss to follow-up, especially if participants are lost from the study for reasons relating to either exposure or outcome such as when participants withdraw from a study because they are feeling better, or are “lost” because they die. Misclassification bias occurs when investigators incorrectly categorize participants with respect to exposure or outcome. In a retrospective study of 378 children regarding the predictability of caustic esophageal injury from clinical signs and symptoms, it was found that 11 of 80 asymptomatic children had significant burns.¹⁴ There is a possibility that these “asymptomatic” children were misclassified because of lack of rigorous written documentation of symptoms or signs within the medical charts. In addition, studies that use “cause of death” as an outcome may be vulnerable to misclassification as well. In a large study comparing 414 poison center (PC) deaths with 7050 poisonings in the corresponding Vital Statistics database, the medical examiner and a medical toxicologist adjudication panel concurred on “cause of death” in only 66%, which the authors interpreted as only fair (ie, less than good) agreement.²⁶ Thus, when investigators define “cause of death” as their study outcome, their results may be biased depending on which specialists are used to provide the “cause of death” interpretation.

Bias is best minimized through careful study design. It is important to precisely define the study question and the population at risk and to carefully define rigorous inclusion and exclusion criteria. The outcome should also be defined precisely. During data acquisition the best way to reduce bias may be to keep study personnel gathering exposure data blinded to outcome, and vice versa. Often, it may also be advisable to keep study participants unaware of their status within a study to the extent that it is ethical (thus, “double-blinded”—neither investigators nor participants are aware of the participants’ status within a study). Use of placebos or “sham treatments” is a way to facilitate blinding. One of the strongest criticisms of a 1995 trial of HBO for the prevention of delayed neurologic syndromes after CO poisoning³⁶ has been the failure to blind patients and investigators to the treatment in question,³¹ a flaw that was corrected in a follow-up study published in 2002.⁴² It is inevitable that some degree of potential bias will be present in any clinical study. Such bias should be reviewed in the analysis, and estimations of its magnitude and direction (bias toward or away from rejection of the null hypothesis) should be considered.

Unlike selection and information biases, which are errors introduced into studies primarily by the investigators or participants, confounding is a special type of problem that may occur within a study as a result of interrelationships between the exposure of interest and another exposure. Confounding is a bias wherein an observed association is not a

product of cause and effect but instead results from linking of the exposure of interest to another associated exposure. Studies pertaining to adverse effects of drugs of abuse are especially prone to confounding by variables such as concomitant caffeine use, alcohol use, tobacco use, nutritional deficiency, and/or psychiatric illness. Analytic studies may restrict characteristics of enrolled participants or match participant characteristics between comparison groups in an effort to reduce confounding. Accordingly, it has been suggested that future studies on delayed neuropsychiatric manifestations following CO poisoning control for potential confounding from depression and cyanide exposure.²⁷ During data analysis, confounding can often be controlled through stratification of data into subgroups or through multivariate analysis techniques.

Randomization is of central importance in clinical trials. It prevents selection bias and insures against unintended bias. It is also an important method to assure that unsuspected confounding factors are equally distributed between treatment groups within interventional studies. The four common types of randomization include (1) simple, (2) block, (3) stratified, and (4) unequal randomization. The simple method is equivalent to tossing a coin for each participant who enters a trial, such as heads = active, tails = placebo. Generally, a random number generator is used for this type of randomization. Block randomization is often used to guarantee balance in numbers during a clinical trial. The basic idea of block randomization is to divide potential patients into m blocks of size $2n$, randomize each block such that n patients are allocated to A and n to B, and then to choose the blocks randomly. Less common is stratified randomization to prevent imbalance in prognostic factors that may confound estimating treatment effect. Stratified randomization achieves balance within important subgroups. For example, using block randomization separately for diabetics and nondiabetics in a cardiovascular trial. And finally, unequal randomization may be used when two or more treatments under evaluation have a cost difference such that it may be more economically efficient to randomize fewer patients to the expensive treatment and more to the cheaper one.

In order to improve the reporting of clinical trials, and to improve the recognition and interpretation of biases within them, guidelines referred to as the Consensus Standards of Reporting Trials (CONSORT) have been adopted by many medical journals.³⁰ The CONSORT guidelines provide a checklist to allow authors to systematically and uniformly report data and limitations. When interpreting published studies, it is also important to consider the potential for publication bias. Publication bias refers to the tendency for researchers, editors, and pharmaceutical companies to handle the reporting of studies with positive results differently from those with negative or inconclusive results.³⁸ Many journals now require that researchers register all planned clinical trials into a registry as a prerequisite for subsequent publication.

BIASES INHERENT IN STUDIES USING THE AMERICAN ASSOCIATION OF POISON CONTROL CENTERS DATABASE

The NPDS database of the AAPCC is an ambitious effort to catalog and describe the epidemiology of poisoning in the United States and Canada. These data serve to help identify new poisoning epidemics, focus prevention and education efforts, guide demographic and economic poisoning analyses, and guide implementation of public health policies. It is a desirable goal to use this database in defining the scope of toxicity for particular xenobiotics and as a clinical research tool. In this regard, it is important to understand the biases inherent in the current database.

It has been suggested that selection bias might exist within PC data if poisoning is unrecognized as a cause of illness or if a caregiver has no questions pertaining to the management of a recognized poisoning.²² Indeed, a survey of 170 emergency physicians in Utah found that 53% admitted to using a PC for symptomatic acute overdoses, and only 10% contacted PC for the purposes of reporting cases to the national database.¹⁰ Such selection might result in a bias of PC data toward more severe cases. On the other end of the spectrum, two large investigations have found selection bias in PC data suggesting that fatal poisonings may be severely underrepresented.^{19,26} It is interesting to note that in a 2004 report of the Institute of Medicine,²¹ the estimated range of annual fatal poisonings in the United States was from approximately 1000, derived from AAPCC data, to more than 30,000, derived from other databases. A study of potential spectrum bias in PC utilization found that one ED reported 95% of cyclic antidepressant overdoses, 33% of venomous snakebites, and only 3% of inhalation exposures.¹⁷ Further complicating the interpretation of PC data are the findings that such data may also be biased regarding geographic distribution of callers,² age,³⁴ ethnicity,^{2,11,34,41} and socioeconomic status.⁴¹

Knowledge of information bias within NPDS data is less well characterized. Phone interviews of callers, many under duress, are certain to be subject to recall and interviewer bias. A comparison of rural hospital chart data to the NPDS database demonstrated deficiencies in PC reporting and in clinical information transfer to the NPDS database.²⁰ Loss to follow-up remains a problem for many PCs, and misclassification of poisonings by health care professionals inadequately trained in medical toxicology remains too common. The clinical conundrum of the unwitnessed ingestion frequently becomes an issue in PC-derived studies designed to create triage policies. Some children having never ingested a xenobiotic of concern may be misclassified as an exposure and may be improperly analyzed.²⁵

Another potential weakness of PC data involves potential misclassification of substances considered by regional consultants and caregivers. Postmortem toxicology can be a surrogate marker for the accuracy of exposure information reported to PCs in fatal cases. Previously, a putative analysis was undertaken at the New Jersey PC to characterize the

discordance between PC consultation and postmortem toxicology.¹⁶ The researchers found that in 41 of the 206 (19.9%) fatal cases receiving poison center consultation, substances were found at the time of postmortem examination that were not considered in the poison center consultation. This study highlights the potential for discordance between exposures considered and those confirmed by forensic toxicologists. The reasons for discordance may include a lack of thorough history taking or a cognitive bias to the substances initially reported.

Despite the large volume of descriptive poisoning data available, it has proven difficult to derive valid, clinically useful conclusions from either the NPDS database or from published case reports.⁶ One suggested means through which to minimize information bias in descriptive toxicology is through the use of improved data collection charts.⁷ One large data collection effort underway to address this particular issue is the Toxicology Investigators' Consortium (ToxIC), supported by the American College of Medical Toxicology, a prospectively collected data registry of patients seen by medical toxicologists at myriad hospitals and medical centers across the United States. Other researchers have found it useful in clinical studies to transform PC data collection from a passive to an active process through the use of specific research instruments.²⁸ Further efforts are required to reduce and to quantify the impact of selection, interviewer, recall, misclassification, and information biases within PC data to optimize the value of this important resource.

EVIDENTIARY CRITERIA USED TO LINK CAUSE AND EFFECT

As was illustrated in Table 138–5, association of an exposure to an illness does not necessarily equate to cause and effect. In assessing causation, it must be determined if bias is present in the selection or measurement of exposure or outcome. If a study is unbiased, then the role of chance in the occurrence of the observed association must be explored. If an association is unbiased, unlikely to result from random error, and is not subject to confounding, then assumptions regarding to causation can be derived. Table 138–7 provides a list of evidentiary criteria, first proposed by Bradford Hill in 1965,¹⁸ that are often used to support causation.

TABLE 138–7. Bradford Hill Criteria for Determining Causation

Strength	What degree of relative risk or odds ratio was demonstrated in the analysis?
Consistency	Does the cause and effect hold true in different studies, locations, and populations?
Specificity	Does the effect occur without the cause in question, or vice versa?
Temporality	Does the cause precede the effect?
Biologic gradient	Is there a dose–response effect?
Plausibility	Is the association consistent with the current understanding of the biological system?
Coherence	Is the association compatible with existing theory and knowledge?
Experiment	Was the association demonstrated in a well-designed study?
Analogy	Is there another cause–effect relationship in nature that is similar to the one in question?

In medical toxicology it is virtually impossible to prove causal relationships beyond any doubt. The goal is to build empiric evidence so that associations can be confirmed or refuted with conviction. However, many toxicologists deem clinical trials indicating a lack of benefit from gastric emptying, or indicating a therapeutic benefit of HBO therapy for CO intoxication, unconvincing because of the degree of bias present in all relevant published clinical trials. To address this issue, some consensus works (from position papers to formal consensus studies) attempt to provide guidance to clinical toxicologists regarding interventions where equipoise remains despite published clinical trials. For example, the Appraisal of Guidelines for Research and Evaluation (AGREE) Instrument is widely used in consensus guidelines. The instrument in its present form has been updated as “AGREE II” and is composed of 23 items organized into six quality domains (scope, stakeholders, rigor, clarity, applicability, independence).¹

INFERENTIAL STATISTICAL TESTS

As discussed previously, researchers must devise an appropriate statistical test to determine whether or not their data were arrived at by chance, a process known as inferential statistics. Once the significance level has been chosen, the inferential statistical test of choice depends on the type of data that are being collected. It should be noted that using the wrong statistical test for a given set of data will invalidate the results of a study; thus, choosing the correct statistical test is of paramount importance for research study design, as well as for toxicologists who try to interpret published medical studies.

Once the significance level has been set, then the data must be classified by type. Generally, data are either: (1) categorical/nominal (≤ 2 categories of data with no intrinsic ordering, eg, presence/absence of medical comorbidities), (2) continuous/interval (data along a scale where each value is equidistant from one another, eg, dollar values), or (3) ordinal/ranked (≤ 2 categories of data with clear intrinsic ordering, eg, grade in high school). The method used to compare groups of data thus depends on whether data is categorical, continuous, or ordinal. Most commonly, categorical data are compared in terms of ratios/percentages (Chi-squared test) and continuous data are compared in terms of means (student's t-test) or medians (Mann-Whitney U test). As a general rule of thumb, an ideal analysis involves comparing interval/ratio data between groups due to the fact that this data contains more information than any of the other forms of data. Finally, the number and relatedness of the independent variables for analysis must be determined. Most commonly, two unrelated samples are compared to assess for associations. However, there are times when groups are paired or related, such as in clinical trials with before/after data in the same participants. Additionally, it is possible to use more advanced techniques to compare three or more independent variables at once (Table 138–8).

TABLE 138–8. Parametric vs. Nonparametric Inferential Tests Based on Data Type

<i>Data Type</i>	<i>Parametric Test</i>	<i>Nonparametric Test</i>
Continuous/interval		
Related samples	Paired <i>t</i> -test	Wilcoxon signed rank
Unrelated samples	Independent samples <i>t</i> -test	Mann-Whitney U
≥ 3 groups	ANOVA	Kruskal Wallis
Correlation	Pearson R	Spearman rho
Nominal/categorical		
Related samples	Chi-squared Fisher exact	McNemar
Unrelated samples	Chi-squared Fisher Exact	Mantel Haenszel trend
≥ 3 groups	Chi-squared	Cochran-Armitage
Correlation	Kappa	Spearman rho
Ordinal/Ranked		
Same scales	Not applicable (NA)	Mann Whitney U
Different scales	NA	Wilcoxon signed rank
≥ 3 groups	NA	Cochran-Armitage
Correlation	Spearman rho	NA

Inferential statistical tests are generally classified into parametric versus nonparametric techniques. This distinction is based on the fact that statistical tests make varying assumptions with regard to the population parameters that characterize the distributions for which the test is employed. Parametric tests generally make more stringent assumptions upon the data to produce valid results, while nonparametric tests make few if any assumptions about the data parameters and can thus be thought of as a “backup” test if the parametric assumptions are not met. For example, the *t*-test assumes that the two groups being compared are independent of each other, and that the dependent variable is continuous and normally distributed along a bell-shaped curve (also known as a Gaussian distribution). Similarly, the Chi-squared test assumes independent observation from a random selection of a given population with a large enough sample size such that any cell in the resultant 2×2 table is greater than five. A violation of one or more of these basic assumptions renders the test results invalid and mandates application of the nonparametric versions of these tests. A summary of common parametric and nonparametric tests based on data classifications is illustrated in Table 138–8.

EVALUATION OF DIAGNOSTIC TESTS AND CRITERIA

In clinical practice it is often useful to have a test, which may be a laboratory result or clinical paradigm, to help arrive at a diagnosis or predict an outcome. For instance, historical questionnaires, capillary blood lead concentrations, and venous blood lead concentrations might all be used to identify children at risk of neurocognitive injury from plumbism.⁹ However, each of these approaches is likely to have certain disadvantages in terms of effort, cost, discomfort, and/or accuracy. Targeting lead evaluation and therapy in children on the basis of exposure history is expected to be easy and inexpensive, but may not identify some children with significant poisoning; thus, the test may be susceptible to being falsely negative. Capillary blood testing is more costly and uncomfortable and may be susceptible to false-positive test results because of environmental lead dust present on fingertips. The possibility of false-positive or false-negative results must be considered

with any diagnostic test (Fig. 138–4).

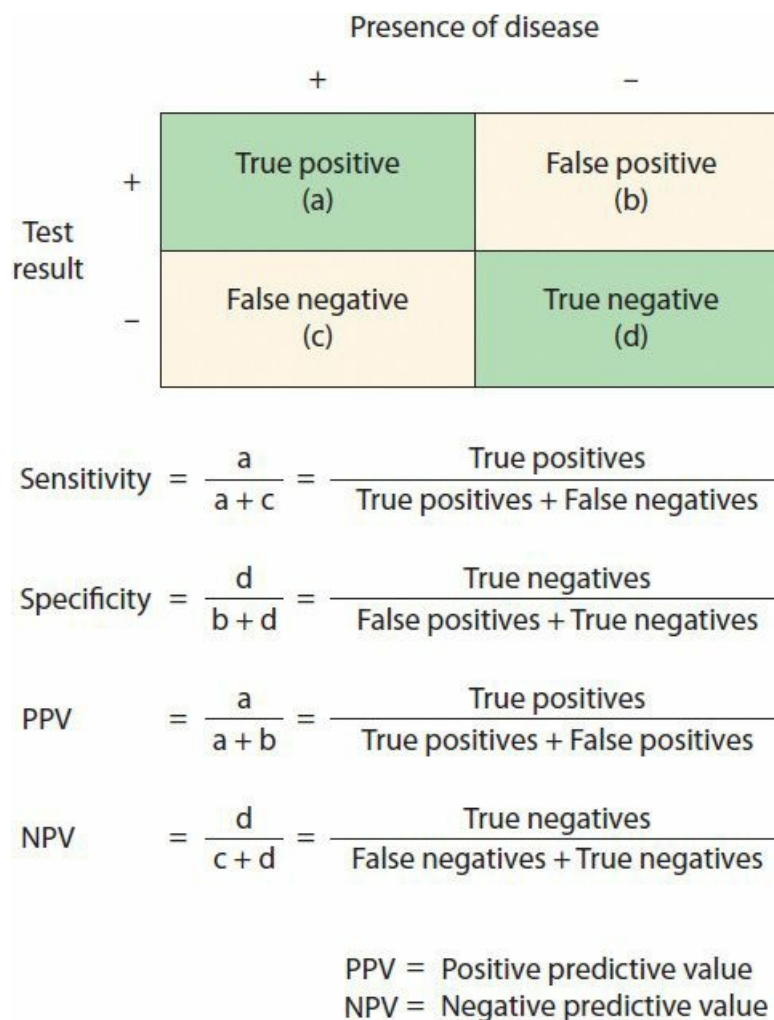

FIGURE 138–4. Possible results of diagnostic testing and the statistical characteristics used to describe the utility of diagnostic tests. The letters a, b, c, and d represent the numbers of tested individuals with or without the disease of interest.

The utility of diagnostic testing is often described in terms of sensitivity, specificity, predictive value of a positive test (PPV), and predictive value of a negative test (NPV). A cross-sectional design is often used to study diagnostic tests, as we seek to determine the prevalence of positive tests among the diseased (sensitivity), and the prevalence of negative tests among the healthy (specificity). A perfect test would be highly sensitive and specific, but this is seldom possible. A highly sensitive test (eg, D-dimer to assess for pulmonary embolism) is often used in screening programs because they rarely lead to false-negative diagnoses. Specific tests (eg, cardiac troponin to assess for acute coronary syndrome) are typically used to “rule-in” a diagnosis, as they rarely yield false-positive results. Whereas sensitivity and specificity are inherent properties of a diagnostic test applied to a given population, the probability of disease—based on the results of a test—is highly dependent on the prevalence of disease within the population being tested. The PPV is the probability of having disease in a patient with a positive test; the NPV is the probability of not having disease when the test result is negative. Numerous studies have tried to examine the utility of vomiting, leukocytosis, hyperglycemia, total iron-binding capacity, and radiographic findings in predicting toxicity after acute iron overdose. In a retrospective assessment of 40 adults with oral iron overdose, vomiting was found to predict a serum iron concentration above 300 µg/dL with a sensitivity rate of 84%, specificity of 50%, NPV of 44%, and PPV of 87%.³³ This suggested that the presence of vomiting should raise concern for iron toxicity but that the lack of vomiting was not particularly reassuring. Figure 138–4 illustrates the calculation of the sensitivity and specificity rates, as well as the PPV and NPV. It is important to remember that these calculations, too, are subject to bias and are best presented with CIs.

Galen, an influential physician from the second century, remarked of his clinical trial, “All who drink of this remedy recover in a short time, except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases.” Unfortunately, error in contemporary clinical investigation of poisoning tends to be more insidious than the error in logic in Galen’s conclusion, and skillful scrutiny of published research remains an important endeavor.

SUMMARY

- Medical toxicology has embraced the vision of incorporating “evidence-based, or literature-based, medicine” into practice.

- Randomized clinical trials, although a noble goal, are rare and have proven difficult to perform within the discipline.
- As toxicologists move beyond descriptive data reporting, there remains great potential for scientific advancement in the field of toxicology via observational, hypothesis-testing, clinical research.
- Clinical investigators are charged with the imperative to perform studies based on sound epidemiologic principles.
- All studies, by nature of population sampling, are at the mercy of chance, but such random error can be quantified using statistical techniques.
- Systematic error (bias) can be limited, but not entirely excluded, through careful study design.
- Clinicians interpreting published toxicologic research need to thoroughly evaluate a study's research objectives, design, data acquisition, analysis, and conclusions before applying the results to patient care (Table 138–9).

TABLE 138–9. Questions to Consider When Evaluating a Study

Research objectives What is the study question? What is the studied population?
Study design What type of study was performed? How were participants recruited and enrolled? Why were participants excluded? What was the nature of the comparison group?
Data accrual How were the data collected? Are the exposures and outcomes clearly defined? Are the observations reliable and reproducible? Was randomization and/or blinding used? Were participants lost to follow-up?
Analysis Are the results statistically significant? Are the results clinically significant? Are potential confounding variables controlled? Was the study powered to detect important differences?
Conclusions Are the conclusions justified by data?

- Future epidemiological investigation should allow more valid conclusions to be drawn regarding the associations between exposures and outcomes, or regarding the value of treatments for poisonings, discussed in the preceding chapters of this text.

139 DRUG DEVELOPMENT, ADVERSE DRUG EVENTS, AND POSTMARKETING SURVEILLANCE

Louis R. Cantilena

This chapter will focus on drug-induced diseases that occur as expected or unexpected adverse drug events (ADEs), as a drug–drug interaction or an ADE causing an untoward drug–disease interaction. Also included in this chapter is a discussion of an approach to the diagnosis of drug-induced disease, an overview of the new drug approval process in the United States, monitoring of drug safety postapproval, and the suggested role for the medical toxicologist in the discovery, reporting, and prevention of ADEs.

ADEs are defined as untoward effects or outcomes associated with use of a drug. In this chapter, the word “drug” will be used for a pharmaceutical product and includes prescription and nonprescription medications, and dietary supplements.

In the United States, all new prescription and nonprescription medications must be shown to be both safe and effective in order to achieve approval by the US Food and Drug Administration (FDA), a prerequisite for marketing and sale. Dietary supplements fall outside of this legal requirement ([Chap. 45](#)).

HISTORY OF THE UNITED STATES DRUG APPROVAL PROCESS

The evolution of drug product regulation in the United States has generally been reactionary; that is, most drug regulations were created in response to medicine related disasters at various times in our history. Prior to 1900, there was no requirement for a drug or medical device manufacturer to demonstrate that the product actually worked (efficacy), was safe when used as directed, or was made to be within precise manufacturing specifications. In addition, no laws existed that required labeled claims be proven valid. Any product could be sold as a company desired and it was left to the consumer or health care professional to determine if the products actually worked and were safe. Initiation of medicinal product regulation and the overall evolution of the US drug law and regulations are closely linked to specific medical product disasters that occurred during the twentieth century in the United States. Relatively recent changes in US drug approval law further changed drug review timelines and prioritization of drug application reviews. Most recently, specific provision of the FDA authorization has designated certain medication classes, such as antimicrobials, to receive extended patent protection as an incentive to develop new medications in an area where growing antibiotic resistance is on the rise and has become a public health concern.

Examples of the pre-1900—or preregulation—marketed products include aspirin containing heroin sold as cough syrup and wine with cocaine to enhance sales of the alcoholic beverage. There was no legal requirement for systematic testing of products to determine content or the presence of possible adulterants in product formulations. The Pure Food and Drug Act of 1906 required pharmaceutical manufacturers to meet a standard for the concentration and purity of the drugs they marketed. However, the burden of proof was on the FDA to show that the drug was incorrectly labeled or that the advertising or label was false or misleading. To a large extent this is the current regulatory state for dietary supplements.

The Food, Drug, and Cosmetic Act of 1938 resulted from a tragedy in which more than 100 patients (mostly children) died from poisoning by an excipient used in an oral solution of sulfanilamide, an antibiotic. Massengil, a pharmaceutical company, in an attempt to improve the palatability of a pediatric formulation of a sulfanilamide, added the solvent diethylene glycol to the formulation. Diethylene glycol is a sweet-tasting, but nephrotoxic hydrocarbon. Only after almost a full year of marketing were cases of renal failure and death reported in sufficient numbers to alert authorities to the extremely toxic nature of the product. The Food, Drug, and Cosmetic Act of 1938 accomplished the following:

- Required companies to list the ingredients on each product label
- Required companies to provide the known risks concerning use of the product to physicians or pharmacists
- Made illegal the misbranding of food or medical products
- For the first time, required companies to test their products for safety before being sold

Drugs already marketed before 1938 were exempt from the requirement ([Chap. 1](#)).

The Kefauver-Harris Amendments to the Food and Drug Act of 1962 resulted from the drug approval disaster that occurred in Europe and not in the United States. An application in the early 1960s for the approval of α -N-phthalylglutaramide (thalidomide), a sedative hypnotic already marketed in Europe at the time, was submitted to the FDA for review and approval. The sedative hypnotic had a rapid onset and short duration of action, did not affect ventilation, did not cause a morning-after effect, and was inexpensive. Dr. Frances Kelsey, a medical officer at the FDA, delayed approval by asking the sponsor to clarify several issues in the reportedly poorly organized new drug application (NDA). In the interim, an unusual teratogenic effect, phocomelia, or limb misdevelopment, was linked to the use of thalidomide in Europe. Congressional hearings on the “almost” approval for marketing in the United States resulted in the Kefauver-Harris Act of 1962, which required a drug manufacturer or sponsor to do the following:

- File an investigational new drug (IND) application prior to initiating a clinical study with a drug in humans
- Demonstrate that the drug was effective for the condition that it was being marketed to treat
- Provide adequate directions for safe usage of the drug

The act also was not retroactive and drugs that were already on the market were exempt from these new requirements. However, the Waxman-Hatch Act of 1983, among other things, incentivized companies to establish evidence in support of actual indications for an exempt drug. The effects of this incentivisation were demonstrated when a small pharmaceutical company studied the use of colchicine in gout which the company applied for, and subsequently received exclusivity leading to a 50 fold increase in the price of this ancient drug.¹⁷

Subsequent US food and drug laws that have primarily affected FDA review and approval of products include the following:

1. The Orphan Drug Act of 1983: The act provides financial incentives to drug manufacturers to develop drugs for the treatment of rare diseases and conditions (see <http://www.fda.gov/orphan/designat/list.htm> for a list of drugs that are approved under the Orphan Drug Act). A rare disease is defined as one in which there are less than 200,000 affected persons in the United States, or one affecting more people, but in which the cost of drug development is likely to exceed any potential sales of the drug (<http://www.fda.gov/orphan/oda.htm>). Some perverse outcomes due to marketing exclusivity have resulted. For example, colchicine received 7 years of marketing exclusivity after study of its use in patients with Familial Mediterranean Fever.¹⁷
2. The Prescription Drug User Fee Act (PDUFA) of 1992: The Act requires that manufacturers pay user fees to the FDA for NDAs and supplements to enable the FDA to hire additional reviewers and accelerate the review process. This Act, which has undergone several revisions (the latest in 2007), has proven to be controversial due to the new working relationships created between industry and regulators, and the concern that it may lead to compromises that are not in the best interest of public health.

The question remains as to whether or not the introduction of user fees and their associated mandate for shorter FDA review times for NDAs have had the desired impact.³⁷ A recent comparison of review times over the first four Prescription Drug User Fee Act (PDUFA) authorizations did not find a substantial improvement.⁶ Compared with European Medicines Agency (EMA) and Health Canada, the analogous agencies to FDA in those regions, the FDA already had, and has maintained, significantly shorter review times over the past decade.⁶ Additionally, some believe that the shorter review times for FDA approval appear to be associated with an increased likelihood of drug withdrawal and black box label modification of the drug label postapproval,² although others do not concur.⁴⁰ The debate on this issue intensified during the controversy involving the cyclooxygenase-2 (COX-2) inhibitor antiinflammatory drugs. This widely publicized withdrawal and press coverage of the related litigation resulted in congressional hearings on the review practices and monitoring of drug safety by the FDA. The legislation has evolved to attempt to provide FDA with regulatory authority, adequate funding, and to encourage scientific exchange between the FDA and sponsors of drug products during the drug development process with the goal of improved quality and efficiency of the development process. PDUFA V, the fifth reauthorization of the FDA covering the period of 2013 to 2017, was recently approved.

3. The Dietary Supplement Health and Education Act (DSHEA amendment) of 1994: The Act removed from FDA the authority to require proof of safety or efficacy prior to marketing of products considered dietary supplements (including herbal remedies). Only when the manufacturer of a product makes a specific health claim, such as “treats congestive heart failure,” does the FDA have premarketing approval authority. That is, the use of structure or function claims, such as “supports heart function,” obviates the need for approval. Furthermore, rather than placing on the manufacturers the burden of proof for safety and efficacy of a product, the FDA is required to determine that a product is unsafe to prevent sale and distribution in the United States. Few dietary supplements have reached that benchmark.
4. The FDA Modernization Act of 1997: Among other things, the Act allowed for an accelerated drug approval process for the treatment of life-threatening illnesses such as AIDS and cancer if the drug has the potential to address medical needs unmet by currently available drugs. Many of the accelerated drug approvals rely on efficacy results derived from surrogate markers linked to the ultimate indication for the drug. For example, the protease inhibitors were approved on the accelerated track for the treatment of AIDS based on their demonstrated ability to reduce HIV viral load in

preapproval clinical studies. Although practical, this may not be ideal and has led to additional authorities granted in later legislation (such as the Food and Drug Administration Safety and Innovation Act {FDSIA}).³²

5. The Pediatric Research Equity Act of 2003: The Act requires manufacturers to study drugs being submitted for approval for a claimed indication in children. The FDA provides incentives such as patent extension and marketing exclusivity for performing these evaluations. As a result more data from children are being provided to guide therapeutic use of medications in this patient group, at the expense of allowances for marketing exclusivity to those manufacturers who provide such data.¹⁹
6. In 2007, the Food and Drug Administration Amendments Act (FDAAA) increased FDA responsibilities and authorizations primarily aimed at improving product safety. Specified deadlines for drug application reviews were added as well as the creation of a priority for FDA review based on indication and potential benefit of the candidate drug for a disease population. Four of the provisions of FDAAA reauthorize past legislation: PDUFA, the Medical Device User Fee Amendments of 2007 (MDUFA), the Pediatric Research Equity Act of 2007 (PREA), and the Best Pharmaceuticals for Children Act of 2007 (BPCA).

FDAAA gives authorization to FDA to require postmarketing studies, primarily of drug safety, including surveillance and clinical trials, as well as the requirement that sponsors incorporate Risk Evaluation and Mitigation Strategies (REMS) in their proposed marketing activities as a prerequisite for product approval. REMS are a mechanism to allow FDA to require proactive risk surveillance for newly approved products or those in which safety signals are detected. The elements of REMS vary considerably among products, and may be applied to both safety concerns and the potential for misuse, as in the case of prescription opioids.³⁸ The impact of these new regulations remains unclear, particularly as to whether still stronger regulatory oversight is needed to protect the public health.

FDAAA also included a requirement for FDA to ensure that clinical trial information is provided to the National Institute of Health's ClinicalTrials.gov Web site. However, despite the mandate, most trials are not reported within one year of their completion.²⁹

Drug shortages, which have been present for decades, reached crisis levels in 2010. The reasons are multifactorial, but coincide with a time when an empowered FDA began enforcing high manufacturing standards at production sites around the nation and the world.¹⁶ Although many of the concerns leading to plant closure were not associated with patient harm, the proactive stance primarily affected generic drug manufacturers,³ initially mainly those producing oncology drugs that were unable or unwilling to respond to standard regulations. The shortage of important drugs had significant medical and ethical consequences including delays in care and medication errors. Furthermore, economic consequences of the use of more expensive (and potentially less effective) alternative drugs and development of a "gray" market led to higher costs.³³ Some health systems turned to compounding pharmacies, which were largely unregulated. As this practice grew, new concerns such as interstate transport of compounded medications and safety risks from lax oversight became prominent.⁷

7. In 2012, the bipartisan passage of FDSIA again reauthorized PDUFA (now PDUFA V).³¹ This law included two noteworthy new FDA responsibilities and authorities: the establishment of a user fee requirement for generic drugs and for biosimilar (genericlike) biologic products similar to what is called the innovator product for drugs, and a new category of drug application designation called the "breakthrough therapy" designation. The breakthrough designation allows FDA to assist drug developers in an expedited review and approval process of a product application when there is preliminary clinical evidence that shows the drug may be a substantial improvement over existing therapies for treatment of patients with life-threatening diseases. Other new initiatives include an active effort to include patient groups representative of the affected populations in the overall FDA review processes and some yet to be determined measures to enhance the safety of the drug supply chain. This act allowed FDA to better regulate foreign drug manufacturing facilities to help alleviate shortages, and to require pharmaceutical companies to make the FDA aware of impending drug shortages. In addition, the provisions of the BCPA and PREA were made permanent.

A complete listing of the laws and statutes enforced by the FDA is found on the FDA Web site.¹⁰

THE DRUG DEVELOPMENT PROCESS

Figure 139–1 is a schematic overview of the process for drug development of a new molecular entity (NME). The process begins with the preclinical evaluation of the candidate drug. During this evaluation, preclinical toxicologic testing is performed in more than one animal species, and other testing includes product stability, good manufacturing methods, purity, and potential carcinogenicity. Dose–response relationships in animal models and in vitro receptor binding or surrogate marker effects are often determined at this phase of the evaluation. At this time many manufacturers determine the metabolism of the drug in animal and in vitro human systems. Following this preclinical testing, the sponsor submits an IND application to the FDA for approval to initiate human testing. This application contains all relevant data concerning animal and in vitro toxicology testing, product manufacturing and purity, and a protocol for using the drug in initial human

investigation. Within 30 days, the FDA must review the IND application and either allow the proposed human study to proceed or inform the sponsor that additional data or preclinical (eg, animal) study is required before clinical testing of the candidate drug can begin.

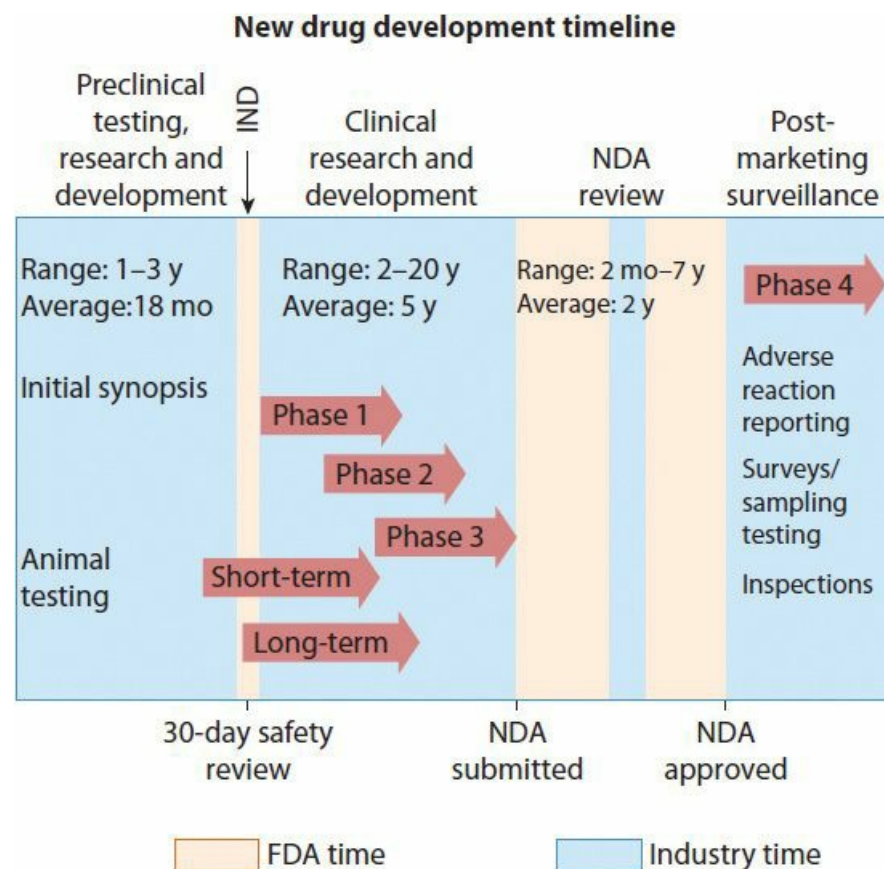

FIGURE 139–1. Schematic representation of new drug development. FDA = US Food and Drug Administration; IND = Investigational New Drug; NDA = New Drug Application. (From www.fda.gov.)

The clinical study of new candidate drugs is divided into four basic phases.

Phase 1 clinical testing involves a relatively small number of participants with the primary aim of determining the safety and toxicity of the drug. Many phase 1 studies will also determine the human pharmacokinetics and metabolism of the drug. Phase 1 studies are normally conducted in 20 to 100 healthy volunteer participants, with the notable exception of phase 1 studies for cancer chemotherapeutics, which enroll only patients with cancer.

Phase 2 clinical testing is designed to determine the potential efficacy of the drug product in humans, usually at varying levels of exposure to the drug candidate. In this phase, approximately 100 to 300 participants are usually studied. In phase 2 clinical trials, participants generally have the diseases for which the drug is intended or are capable of demonstrating the appropriate, validated, biologic surrogate marker to indicate response to the drug. An example of this would be when a drug intended for early treatment of acute coronary syndrome is tested to show that it can inhibit *in vivo* platelet function after oral dosing in human study participants.

Phase 3 clinical drug studies usually involve large scale clinical trials in the actual population for which the drug is intended for use. Typically, this phase of drug development will involve testing a treatment cohort versus a control treatment of several hundred to several thousand patients who have the target disease, depending on both the prevalence of the disease and effectiveness of the drug. The primary goal of phase 3 studies is to determine the safety and efficacy of the candidate drug in the actual intended patient population in question, under conditions similar to the anticipated medical use. At the completion of phase 3, an NDA (request for approval to market) is submitted to the FDA. A candidate drug completing phases 1, 2, and 3 can thus be approved for marketing after study in only 2000 to 4000 patients. In the setting of a fast-track approval or under the Orphan Drug regulations, substantially fewer patients will receive the drug before its approval for marketing. The relatively small number of human exposures to a new chemical or biologic entity prior to approval for marketing is an important factor that limits the sensitivity of the drug approval process to detect uncommon ADEs.

Toward the end of the review cycle, the FDA often seeks the external advice of its constituted advisory committees prior to their approval decision, especially in the setting of an uncertain risk–benefit profile of a candidate drug. FDA advisory committees generally are organized by therapeutic areas and are composed of medical professionals, primarily from academia, as well as biostatisticians, a patient representative, a consumer representative, and a nonvoting industry representative. These same advisory committees also convene to consider postapproval safety or efficacy data when FDA is considering an important change to a drug label or other postapproval regulatory action. Generally, the FDA prepares

questions for the committee members and provides an FDA briefing document containing a detailed data analysis and background of the issue from the FDA perspective as well as a briefing document prepared by the drug sponsor containing corresponding information. Committee members comment and vote on the FDA questions during the proceedings. For a new drug approval, one question generally includes a yes or no answer as to whether or not the committee member believes that the drug can be marketed with an adequate risk–benefit profile. The advisory committee vote is technically nonbinding for the FDA, but the FDA generally follows the advice of the committee. A recent issue of concern is the fact that some members of FDA advisory committees with perceived conflicts of interest are granted waivers by FDA to participate.²³ The appearance of conflict of interest on an advisory committee can have a significant impact on the drug approval process, and the FDA has begun to decrease the number of committee member waivers.

At the conclusion of the NDA review process and, at times, following an Advisory Committee meeting on the application, the FDA may issue an approval for marketing the new product. On occasion, the FDA issues an “approvable” letter, indicating that the product is potentially approvable but additional data will be needed before final approval can be granted. Examples of additional data required in this setting include further clinical study of a specific drug interaction, use of the drug in a specific patient population, or extension of the submitted drug stability testing. Once approval of the drug is given by the FDA, the next phase of drug development begins as discussed separately below.

Phase 4 Drug Development: Postmarketing Surveillance

Every drug, therapeutic biologic product, or medical device carries with it some potential risk. If society required that only “completely” safe drug products could be marketed, the drug approval process would likely take decades and few if any new drugs would be made available. Therefore, the FDA and the pharmaceutical industry rely significantly on postmarketing surveillance for further safety information regarding the toxicity of a medical product after approval. A postmarketing surveillance system is in place to monitor postapproval drug safety. These systems are intended to detect unanticipated or previously unrecognized adverse events or to identify an at-risk population in whom the safety profile differs from that which was expected prior to marketing. Individual pharmaceutical manufacturers are responsible for monitoring the safety of their products and regularly reporting any detected ADEs to the FDA. The FDA postmarketing surveillance program (MedWatch) for all medical products is a parallel system in place to monitor drug and medical device safety. This system relies on spontaneous reports by health care professionals or patients regarding the occurrence of deleterious effects associated with the use of a medical product.

Because manufacturers are also required by law to report ADEs associated with use of their products to MedWatch, the FDA database contains one complete data set called FDA Adverse Event Reporting System (FAERS), that was renamed from AERS in 2010 following its enhancement and integration of device-related data.³⁴ Because the MedWatch system is passive in nature, the estimated overall rate for adverse event reporting is estimated at only 1% to 10%. Despite this, the number of serious adverse events reported to MedWatch increased between 1998 and 2005,²⁶ although the completeness of the reports remains poor.¹³ Improved attitudes toward reporting, perhaps due to an appreciation of the risk of error and adverse drug effects, leads to better MedWatch reporting.¹² Both, the adverse event reports from MedWatch and those that are submitted from product manufacturers are entered into the FAERS database. This database is fully computerized and therefore easily searchable and contains adverse event reports from human drug and biologic products. The system contains more than 7 million reports, entered since 1969, and is growing substantially. In 2012 there were nearly 1 million reports submitted to FAERS. Approximately 95% of the total reports in the system are generated by the manufacturers and the remaining 5% are submitted via the MedWatch system.

The primary goals of the MedWatch system are the following:

- To increase awareness of drug-and device-induced disease.
- To clarify what should (and should not) be reported to the agency.
- To facilitate reporting of adverse effects by creating a single system for health professionals to use in reporting ADEs and product problems to the agency.
- To provide regular feedback to the health care community about safety issues involving medical products.⁹

Establishing causality for a specific medical product is not required before submission of a MedWatch report. The FDA is primarily interested in the reporting of serious adverse events, or an ADE previously not associated with the drug being administered, whether or not a causal relationship is established. Although any potential ADE should be reported, an event is considered serious and must be reported when the patient outcome is one of the following:

- Death: If the death is suspected to be a direct result of the adverse event
- Life threatening: If the patient was considered to be at substantial risk of dying at the time of the adverse event or the use or continued use of the product would result in the patient’s death (eg, gastrointestinal hemorrhage, bone marrow suppression, pacemaker failure, and infusion pump failure that permits uncontrolled free flow and results in excessive drug dosing)
- Hospitalization (initial or prolonged): If admission to the hospital or prolongation of a hospital stay resulted from the

adverse event (eg, anaphylaxis, pseudomembranous colitis, bleeding that causes or prolongs hospitalization)

- Disability: If the adverse event resulted in a significant, persistent, or permanent change, impairment, damage, or disruption in the patient's body function/structure, physical activities, or quality of life (eg, cerebrovascular accidents caused by drug-induced coagulopathy, toxicity, peripheral neuropathy)
- Congenital anomaly: If there is a suspicion that exposure to a medical product before conception or during pregnancy resulted in an adverse effect on the child (eg, vaginal cancer in female offspring from maternal exposure to diethylstilbestrol during pregnancy or limb malformations in the offspring from thalidomide use during pregnancy)
- Requires intervention to prevent permanent impairment or damage if use of a medical product is suspected to result in a condition requiring medical or surgical intervention to preclude permanent impairment or damage to a patient (eg, acetaminophen overdose-induced hepatotoxicity requiring treatment with N-acetylcysteine to prevent permanent damage, burns from radiation equipment requiring drug therapy)

MedWatch reports are easily done through the MedWatch Web site, or by facsimile, telephone, or mail. Physician reports are given priority for review by the FDA in the MedWatch system. A well-documented case of a serious adverse event is a significant and useful contribution to the MedWatch system.

Reports of serious ADEs to the FDA or to the manufacturer can become an epidemiologically detectable signal that can trigger a more detailed investigation, several examples of which are provided later in this chapter. On occasion, serious ADEs detected in the AERS database have led to the withdrawal of products from the US market without conducting additional studies.

Reporting serious ADEs has periodically been encouraged by various health care groups in conjunction with the FDA. Currently, the MedWatch program is supported by more than 140 organizations, representing health care professionals and industry collaborating as MedWatch Partners to help achieve these goals. These organizations include medical societies and organizations such as the American Medical Association (AMA), the American College of Medical Toxicology (ACMT), and the American Academy of Pediatrics (AAP) that have encouraged their members to report to the MedWatch system. As a requirement for hospital accreditation, The Joint Commission mandates hospitals to collect, analyze, and report significant and unexpected ADEs to the FDA.

The primary limitation of the MedWatch system is the exclusive reliance on spontaneous reporting of ADEs. The system is passive in nature and therefore has several important limitations. Significant underreporting is known to occur in such systems. The uncertainty about the significance of a signal in the AERS database is exacerbated by the low estimated rate for adverse event reporting and the fact that the true incidence of the reported ADE is almost never precisely known because the denominator, which is the number of actual exposures to the drug, is rarely accurately known. Despite these limitations, the MedWatch system has detected significant ADEs during the postmarketing period.

Drug regulators must rely on passive surveillance systems like the AERS database to detect potential uncommon or rare but serious ADEs postapproval. This is primarily because a relatively small number of patients or participants are exposed to the drug during phases 1 to 3 prior to approval for marketing. For example, to detect an uncommon ADE occurring in approximately 1 of 5000 individuals exposed to a drug with 95% probability that the ADE resulted from exposure to that drug, approximately 15,000 patients would have to be exposed to the drug. In a balanced (equal numbers of drug and placebo recipients) placebo-controlled clinical trial, 30,000 participants would need to be enrolled. Premarketing clinical studies (phases 1, 2, and 3) are usually inadequate to detect rare ADEs, ADEs that are incorrectly diagnosed, or ADEs that result from a drug interaction that may not have been tested in the development program.

An example of a rare ADE not detected until postmarketing involves the drug felbamate, which was approved by the FDA in September 1993 and subsequently found to be associated with aplastic anemia during postmarketing surveillance. Felbamate induced aplastic anemia had not been detected during the drug development program. By July 1994, nine cases had been reported from an estimated 100,000 patients exposed to felbamate in the United States.²⁸ Most of the aplastic anemia cases occurred in patients who had taken the drug for less than 1 year. The nine cases represented an approximate 50-fold increase in aplastic anemia over the expected rate in the population with the very low background rate of two to five cases per million per year allowing the FDA to attribute this rare condition to exposure to felbamate.

The primary role of the MedWatch system is to generate a hypothesis for potential association of an ADE with a specific drug. These hypotheses are sometimes further tested in subsequent phase 4 investigations. An example of this "hypothesis generation" function of MedWatch was the question of whether phenylpropanolamine (PPA) caused hemorrhagic stroke in patients using nonprescription diet suppressants or cough and cold preparations containing PPA. In the early 1990s, the Spontaneous Reporting System (SRS; now AERS) detected a potential association of hemorrhagic stroke and nonprescription use of PPA. An industry-sponsored prospective, case-controlled study was designed to determine if such an association existed. The multicenter study demonstrated that an association did exist, especially for women aged 18 to 49 years. The Nonprescription Drug Advisory Committee (NDAC) of FDA reviewed this study and the associated MedWatch data in the fall of 2000 and decided that the evidence supported such an association. The committee advised the FDA to remove PPA from the market, which occurred a short time later. Although the entire process of signal identification from MedWatch to presentation of results from the prospective epidemiologic study required nearly a decade for PPA, the process demonstrates the value of the hypothesis-generating ability of the MedWatch system.

Potential outcomes of a safety signal detection for a marketed drug include dose reduction in all or certain high risk patient populations, restriction of the sale of the specific drug to a more medically supervised environment or the development of a patient registry to more closely monitor use, and removal of the drug from the market. These options are further discussed later in this chapter.

Other types of phase 4 safety investigations include clinical studies, comparative studies with the new drug versus a competitor, or a special population study or drug interaction study when suspicion is raised that there may exist a different risk–benefit relationship in certain clinical settings. The enhancement of safety information is the primary goal of most phase 4 studies. Other than the specific prospective study in patient subpopulations, the methods by which phase 4 safety studies are usually conducted are primarily observational and epidemiologic. Main sources of data for the postapproval monitoring of the safety of a drug are the spontaneous reports gathered by both the pharmaceutical manufacturer and FDA. The fields of pharmacovigilance and pharmacoepidemiology are typically employed in the conduct of phase 4 studies. Attributing a serious ADE to a drug solely from MedWatch reports does occur, but it is much more common for the AERS database to produce a signal, suggesting a possible drug-related safety problem.

ESTABLISHING THE DIAGNOSIS OF DRUG-INDUCED DISEASE

The recognition and diagnosis of a drug-induced disease, or an ADE, is an essential skill for all practitioners, and especially for medical toxicologists and clinical pharmacists and pharmacologists. The diagnosis of an ADE is typically established as the result of a systematic medical evaluation. One approach to establishing the diagnosis of drug-induced disease involves consideration of six related questions concerning the patient’s clinical presentation and available medical data, as shown in [Table 139–1](#).

TABLE 139–1. Questions to Consider When Establishing the Diagnosis of an ADE
1. Was the timing of the adverse event appropriate relative to the exposure to the drug?
2. Has the effect noted, which is the suspected ADE, been previously reported?
3. Is there evidence of excessive exposure to the drug?
4. Are there other more likely etiologies responsible for the condition suspected as being an ADE?
5. What is the patient’s response to cessation of a suspect drug (dechallenge)?
6. What is the patient’s response to rechallenge?

ADE = adverse drug event.

The first question concerns the timing of the onset of the adverse event in relationship to the reported exposure to the drug. Perhaps because of publicity or word of mouth, ADEs are sometimes reported to the FDA MedWatch system even when the onset of the adverse event occurs before the first exposure to the suspect drug. A careful reconstruction of the time course of drug exposure and onset of adverse effects is extremely important in assessing causality. The time course differs considerably for different adverse clinical events. An anaphylactic reaction to a drug usually occurs within minutes of exposure, whereas renal insufficiency caused by a drug is not likely to be clinically detectable for up to several days after the exposure. A drug that causes cancer (a carcinogen) may not produce a clinically detectable effect for decades. Establishing a time course is an essential first step in the process of making the diagnosis of drug-induced disease.

The second question is whether or not this adverse effect was reported previously for the suspect drug. An adverse drug effect that occurs commonly is likely to be known before the approval of the drug and therefore is typically found on the initial drug label. For example, respiratory depression and mental status changes were well known before the approval of fentanyl, an opioid agonist. Less common ADEs for drugs that have been on the market for a period of time are sometimes found in case reports in the literature, various medical databases, and in mention of safety related information. These will appear in a revised drug label for the medical product. Previous reports linking the observed adverse effect to drug exposure are very helpful to the clinician trying to establish a significant level of probability for causality in the setting of an ADE.

However, in the setting of a newly approved drug or a previously unreported possible ADE, neither previous reports/medical literature nor the drug label will help establish causality. In this setting, the clinician must rely more on what is known of the pharmacology, the pharmacokinetics, and the anticipated pharmacodynamics of the suspect drug and the timing of the appearance and observed time course of the adverse event. The known pharmacology about the drug should include “target” effects as well as “off target” effects. It is important to put “drug-induced disease” in the differential diagnosis for most patients presenting for medical care. Someone has to be the first to report what is ultimately recognized as an adverse effect. Appropriate vigilance for the possibility of a new ADE significantly increases the probability that a finding can be made early after introduction of a new drug to prevent more widespread drug-induced morbidity or mortality.

The next question to consider is: “Is there evidence of excessive exposure to the drug?” Most ADEs that occur are

predictable on the basis of the known pharmacology of the specific drug. Such ADEs are referred to as type A ADEs.⁵ For example, antihistamines such as diphenhydramine are known to cause significant anticholinergic effects. When a patient presents with mental status changes and clinical findings consistent with the anticholinergic toxidrome after significant exposure to an antihistamine-containing product, the observed effects are consistent with an ADE attributable to the antihistamine. Occasionally, proof of drug excess can come from measurement of the drug in serum. In the case of the patient with a history of atrial fibrillation who exhibits nausea, vomiting, vision changes, and ventricular dysrhythmias, the measurement of an elevated serum digoxin concentration supports the diagnosis of digoxin toxicity or an ADE attributable to digoxin perhaps as an inadvertent or intentional overdose, drug interaction, or change in patient renal function resulting in excessive circulating digoxin concentration. In any case, knowing the pharmacology of the drug is important for establishing the diagnosis of an ADE.

When an ADE is caused by an allergic mechanism or another mechanism unrelated to extent of the exposure to the drug, that is, a type B ADE, evidence of drug excess usually does not contribute to the diagnosis. In this setting, other factors such as allergy history or pharmacogenetic background are weighed more heavily to support the diagnosis of an ADE. Patients are usually not aware of their genetically determined ability to metabolize or react to medications but most patients will recall a previously experienced allergic reaction.

The next issue to address in considering possible causality is whether there are other more likely etiologies that could be responsible for the observed effects. Although it is important to be appropriately vigilant for possible ADEs, it is equally important not to miss an alternative cause for the patient's condition. There are certain clinical settings in which establishing an ADE becomes a diagnosis of exclusion. For example, in the case of persistent fever, the assignment of the diagnosis "drug fever" should not be made until a complete search for infectious causes has excluded this etiology.

A very important factor to consider in contemplating a diagnosis of ADE is "What is the patient's response to cessation of a suspect drug (dechallenge)?" In this case, the pharmacokinetics of the drug and the timing of resolution of the specific condition must be carefully considered. In some instances, the resolution of a type A ADE closely follows the pharmacokinetics of the suspect drug. For example, in the case of acute β -adrenergic antagonist poisoning, cardiac effects resolve in association with decreasing serum concentrations of the drug in question. However, in other instances, onset and resolution of the ADE may not correlate with drug concentrations in the body, for example, in the case of a penicillin rash, which may develop within 1 or 2 days or longer after starting the medication, but may take several days to weeks to completely resolve. In this example of a type B ADE, the resolution of the condition (rash) occurs over a much longer time period than would be predicted by the pharmacokinetics of the drug. When a suspected ADE resolves after discontinuation of exposure to the offending drug, along a predictable time course, the result of this dechallenge would support the diagnosis of ADE.

Lastly, the clinician may have the opportunity or need to rechallenge the patient with the suspect drug. If the rechallenge results in the identical response or effect, this would be considered strong evidence to support a causal relationship for the suspect drug and the adverse event. In the setting of a serious or life-threatening adverse event, it is too dangerous to perform a rechallenge with the suspect drug, in which case the response to rechallenge will not be known. In this setting, the weight of evidence previously discussed will then be the only factors available to assign the probability of causality.

FDA REGULATORY ACTIONS REGARDING SAFETY

When new information about a safety issue for an already marketed drug raises concern at FDA, several regulatory options are available to either attempt to improve the safety of the drug or remove the drug from the US market. The most common regulatory action taken by the FDA is modification of the drug label. These modifications can include restrictions as to whom should receive the drug, what doses should be given for which indications or to which patient populations, what type of monitoring should be performed during therapy, and how long treatment should be administered. When potentially life-threatening safety information is discovered, and the FDA believes that the risk-benefit relationship remains in favor of continued availability of the drug, the FDA can require that a boxed warning (sometimes called a "black box" warning) be carried in the label. A black box warning is the most serious warning placed in the label of a prescription medication. If a black box warning is established, then health care professional advertisements regarding product availability are no longer permitted. Additionally, the manufacturer is required in most cases to send a "Dear Doctor" letter to potential prescribers informing them of the new black box warning. Dear Doctor letters may also be required when the FDA requires that prescribers be notified about a significant change in the drug label warning. An example of current medications with recently added black box warnings is antidepressant medication that now must warn about the increased risk of suicidality if children and adolescents are prescribed antidepressants. The antipsychotic medication clozapine currently has five black box warnings in its drug label for the following attributed ADEs: agranulocytosis, myocarditis, seizures, "adverse cardiovascular and respiratory effects," as well as increased mortality in elderly patients with dementia-related psychosis.

Another option employed by the FDA is the implementation of restricted availability measures to permit continued availability of the drug but only with specified restrictions. For example, use of the drug isotretinoin (Accutane) requires compliance with a multiple component REMS program called iPLEDGE that includes informed consent, prescriber and dispensing pharmacy registration, serial pregnancy testing if applicable, documentation of patient education, and

completion of risk management programs by patients who will receive the medication.³⁶ This option is more commonly used today when there is concern about “off-label” use. The FDA authority to require companies to submit, prior to drug approval, and execute, postapproval, an effective risk management plan is intended to improve both the monitoring and prevention of postapproval adverse drug events and their consequences.

When the FDA believes that a drug can no longer be safely used despite modification of the drug label or any of the aforementioned restrictions, the regulatory threshold is reached to initiate removal of the drug from the market. This occurs when an acceptable risk–benefit relationship for continued availability of a drug product is no longer possible. Table 117–2 in the seventh edition of Goldfrank’s Toxicologic Emergencies contains a compilation of products that were withdrawn or removed from the market in the United States for reasons of safety or efficacy. Some recent additions to that list of drugs include valdecoxib (marketed as Bextra) and rofecoxib (marketed as Vioxx), withdrawn because of recognition of elevated cardiovascular risk associated with their use.¹¹ In the case of the COX-2 inhibitor withdrawals, the precipitating factor for withdrawal was the findings of a strong safety signal for excess cardiovascular mortality and morbidity during the conduct of efficacy studies for other potential therapeutic indications for these drugs. The postmarketing surveillance system did not serve as the initial, precipitating data set for regulatory action in this instance.^{20,27} The manufacturers voluntarily withdrew these COX-2 inhibitors and the majority of the drugs deemed unsafe by FDA from the US market. In many cases, the manufacturer ceases marketing the specific drug after notification by the FDA that regulatory action is being initiated to remove their drug from the market. Only very rarely has the FDA itself actually removed a drug from the market. One example where the FDA did implement removal is the drug phenformin, which was removed by the FDA after due process was completed. In the case of ephedra-containing dietary supplements, the FDA removed these products from the market based on their analysis of safety data obtained from the medical literature and from analysis of cases reported to the MedWatch system. In some cases, the pharmaceutical manufacturers file suit against the FDA to fight or delay the planned regulatory action against the product. The manufacturer’s legal action generally prolongs the time the product remains on the market because the drug usually continues to be sold, while the legal proceedings and appeals proceed through the courts.

Some feel that approval of a drug by FDA should preempt legal action for safety issues identified in the drug labeling. However, the FDA decision-making process regarding drug approval is largely reliant on efficacy and safety data provided by the manufacturer or in the publicly available medical literature. Plaintiff actions, taken against drug and device manufacturers, are sometimes a source of significant publicity and confidential disclosures regarding questionable behaviors practiced by companies that market medicinal products. The patient’s right to tort action against a product’s manufacturer provides an important mechanism to assure drug safety following approval and marketing.⁵ Recent US Supreme Court appeals have challenged this position seeking to reinforce the legal position of federal preemption. In the case of *Wyeth v. Levine*, the manufacturer appealed to the US Supreme Court to uphold the federal preemption status for FDA approved drugs.¹⁸ On March 4, 2009, the US Supreme Court ruled that federal law does not preempt this particular plaintiff from seeking and obtaining a judgment from the product manufacturer because the product was approved by the FDA. The case provided the opportunity to debate the extent of protection afforded by the FDA approval status and the issue of product liability litigation as a part of postmarketing surveillance of drug products in the United States. At the current time, medical devices are governed under a distinct statute in which FDA approval does preempt many forms of litigation.

In recent years, there have been highly publicized drug withdrawals for risk of cardiovascular ADEs such as the COX-2 inhibitors and the recent market withdrawal for rosiglitazone and its subsequent relabeling and reauthorization of marketing for the product for the past two decades. Until recently, the most common reasons for FDA initiated drug withdrawals in the United States have been prolongation of the QTc interval followed by drug-induced hepatotoxicity. These ADEs, as well as the propensity to cause significant drug–drug interactions, are still the primary reasons for drug–safety-related regulatory action in the United States.

Prolongation of the QT Interval

Three significant drug withdrawals in the mid-to late 1990s exemplified a serious drug safety issue with regard to drug related prolongation of the QT interval when administered alone or as the result of increasing plasma concentrations due to inhibition of its metabolism by other medications. The three examples in this category are terfenadine (Seldane), astemizole (Hismanal), and cisapride (Propulsid). Several deaths were reported to the MedWatch system for patients taking these medications. In the case of terfenadine, the initial publication of a case report for polymorphic ventricular tachycardia in the setting of routine use of this nonsedating antihistamine with the self-administration of a known inhibitor of drug metabolism led to FDA funded small prospective clinical studies to confirm a previously unrecognized ability of terfenadine to dramatically alter cardiac repolarization, which can lead to torsade de pointes. The drug was marketed in 1985, cardiac toxicity was detected in clinical use in 1990,²⁵ the FDA funded clinical cardiac safety research performed in 1991,¹⁵ and, ultimately, the drug was withdrawn from the market in 1998. The medicolegal course of the other two drugs is similar except that prospective controlled studies to document the extent of QT prolongation were not performed before regulatory action was taken. These early experiences led to new rigorous regulatory requirements and significant

preclinical screening by manufacturers of all drugs worldwide.

These three drug withdrawals demonstrated that the preapproval assessment of cardiac repolarization effects at that time was incapable of detecting even the most potent dysrhythmogenic drugs during their respective development and FDA review. Based on this dramatic systematic failure, FDA (as well as the European and Japanese drug regulatory agencies) now requires a thorough QT study (tQT) for all new molecular entities.²⁴ These studies are designed to detect as little as a 5-millisecond increase in the corrected QT interval in healthy volunteer participants and must include a positive control to demonstrate the sensitivity of the study to detect this low-level change reliably. Since this new requirement was put in place, no newly approved drugs have subsequently been removed from the US market for QT safety reasons, although questions remain about its cost effectiveness.¹

Significant Drug–Drug Interactions

Removal of mibefradil (Posicor) from the US market is an example of a drug withdrawn from the US market because of postmarketing discovery of a plethora of drug–drug interactions. Mibefradil, a pharmacologically unique calcium channel blocker, was approved by the FDA for the treatment of patients with hypertension and chronic stable angina. The FDA approved mibefradil for marketing in 1997 with the knowledge that the compound possessed the ability to inhibit certain hepatic CYP enzymes; these facts were included on the drug label. The initial labeling for mibefradil specifically listed three drug–drug interactions: astemizole, cisapride, and terfenadine (CYP3A pathway interactions). During the one year that mibefradil was marketed, information accumulated regarding drug–drug interactions with many other drugs and CYP pathways. As the in vitro and in vivo drug interaction data continued to accumulate for mibefradil, the FDA made labeling changes and issued a public warning for these potential drug interactions within 5 months of its initial approval. Additionally, the sponsor distributed a letter to health care professionals warning of drug–drug interactions. In the face of a growing and significant list of drug–drug interactions, and a 3 year international study demonstrating no clinical benefit of mibefradil over placebo for congestive heart failure, the FDA initiated regulatory action. In an unprecedented step for a drug with numerous drug interactions, the FDA requested that it be withdrawn from the market approximately a year after it was approved.³⁰ The FDA felt that the extensive drug–drug interactions could not be addressed by standard drug label instructions and additional public warnings.

Drug-Induced Hepatotoxicity

Another category of ADE of recent concern is those drugs that cause hepatotoxicity. In June 1998, the manufacturer of the NSAID bromfenac sodium (Duract) withdrew this agent from the US market.¹⁴ The NDA was submitted for review to the FDA in 1994 and after 28 months of review was approved. The drug was withdrawn approximately 11 months later after postmarketing discovery of significant hepatotoxicity. Although no cases of serious liver injury were reported during premarketing clinical trials, after introduction to the market, a higher incidence of liver enzyme elevation was found in patients who were being treated with the drug. Postapproval exposure of patients to bromfenac generally resulted in longer periods of treatment than that of the participants in the clinical trials. Because of a preapproval concern by the FDA that long-term exposure to bromfenac could cause hepatotoxicity, bromfenac labeling specified that the product was to be used for 10 days or less. This dosing limitation appeared to be inconsistent with the initial approved drug indication for treatment of a chronic condition (eg, osteoarthritis). Information concerning elevated hepatic enzymes was actually included in the original product labeling. The postmarketing surveillance of this product identified rare cases of hepatitis and liver failure, including some patients who required liver transplantation, among those using the drug for more than 10 days specified on the label. In February 1998, approximately 6 months after approval for marketing, the FDA added a black box warning indicating that the drug should not be taken for more than 10 days. Nonetheless, severe injury and death from long-term use of bromfenac sodium continued to be reported, and ultimately, the sponsor agreed to voluntarily withdraw bromfenac sodium from the market. The withdrawal of bromfenac sodium raised several important questions concerning interpretation of “safety laboratory testing,” such as liver enzymes during the drug development program, and also raised questions concerning the effectiveness of drug labeling.

The FDA has issued specific guidance on how to evaluate drug-induced liver injury (DILI) during drug development.⁸ As with many other adverse drug effects, severe DILI is uncommon so despite extensive study, few cases will be found prior to, and even after, marketing. Properly evaluated for evidence of lesser injury, drug databases may be able to offer insight into the potential for more severe liver injury. One of the common guidelines utilized by FDA is Hy’s law, which states that severe liver injury is predicted by laboratory assessment that includes an alanine aminotransferase of more than three times the upper limit of normal and a bilirubin of more than twice the upper limit of normal in a patient with no other reason for such an abnormality.²² Although imperfect, this is effective in preventing new drugs from obtaining approval and having others withdrawal from the market.

Other Examples of Postmarketing Safety Problems Leading to Drug Withdrawal

One voluntary withdrawal of two separate drugs used in combination serves as an important example of the discovery and

publicizing of an unusual adverse event occurring years after individual drug approval but after a significant increase in the prescription use of the combination product. The drug fenfluramine was approved in 1973 after an FDA review period of 75 months. A significant increase in prescription use of a combination product of fenfluramine with phentermine, for weight loss (referred to as “fen-phen”), began in the 1990s when clinical data suggested that this drug combination was effective in a weight loss program.³⁵ However, use of the fen-phen drug combination was never fully approved by the FDA and was therefore considered an “off-label” guideline usage of the product. The number of prescriptions for the drug combination soared in the mid-1990s. In July 1997, research from the Mayo Clinic reported 24 cases of an unusual form of cardiac valvular disease causing aortic and mitral regurgitation in patients using the fen-phen combination.⁴ The publicity surrounding the potential linkage of this drug combination to an unusual adverse event led to a significant increase in reports of possible adverse events associated with this drug combination. The FDA issued a public health advisory and initiated further epidemiologic studies to ascertain its prevalence. The FDA also encouraged echocardiographic studies of valvular diseases in patients taking fenfluramine or dexfenfluramine either alone or in combination with phentermine. Although at the onset the FDA, the product manufacturers, and the medical community did not expect valvular lesions to be associated with either fenfluramine or dexfenfluramine, the epidemiologic evidence suggested a possible association, leading the FDA to conclude that these agents should be removed from the US market. The potential association of valvular heart disease with these agents is an example of the use of a case-control study to explore a possible causal relationship between drug exposure and an ADE. In this case, it is unclear what the strength of the MedWatch signal was for the possible association of cardiac valvular disease with exposure to the fen-phen combination. The association between cardiac valvular lesions and exposure to the drug combination serves as an example of elucidation of a rare, unexpected ADE as the result of a dramatic increase in the number of exposed patients using a product.

ROLE OF THE TOXICOLOGIST IN THE DETECTION AND PREVENTION OF ADVERSE DRUG EVENTS

Toxicologists can play an extremely important role in ADE diagnosis and prevention, through efforts in patient care, education, and administrative functions. In patient care, it is common for the medical and clinical toxicologists to be the first medical specialists to be consulted for a patient with a potential ADE. Perhaps more than any other medical specialty, medical and clinical toxicologists are likely to include a thorough medication history that also includes prescription and nonprescription products, as well as dietary supplements. The medical toxicologist’s active involvement in the clinical arena, especially in settings in which the initial diagnosis of ADEs can be made, also serves to provide an important role model: the medical toxicologist as an educator to promote the detection and prevention of ADEs often in the academic setting of a medical school and affiliated teaching hospitals. Here, the academic toxicologist can champion the inclusion of education in therapeutics in the curriculum for medical and pharmacy students and house officers, and take an active role in the implementation of the instruction. Assuring that the curriculum in therapeutics includes recognition and prevention of ADEs and medical errors that lead to ADEs could have a significant beneficial impact on the ultimate outcome of the education process toward reduction of preventable ADEs. In addition to making sure that quality information is presented in the curriculum for trainees, the medical toxicologist can often create a special teaching opportunity for this type of education by establishing an elective or, in some cases, required experience in the curriculum for training in therapeutics. Participation in a quality learning experience can significantly impact the graduates’ knowledge of and attitudes toward therapeutics and risk reduction in patient care. Although the Institute of Medicine report on medical errors²¹ did not focus on education initiatives in its main recommendations for reduction of medical errors in the United States, it seems logical that education be considered an important (yet incomplete) tool to improve medication use and prevent ADEs and medical errors with therapeutic agents.

The growth of the discipline of medication safety has provided new venues for involvement of toxicologists. Creation of interdisciplinary teams at many medical centers has allowed a system-oriented approach to the detection, mitigation, and prevention of adverse drug events. These take the form of pharmacy and therapeutics, medication safety, and quality improvement committees, and provide important opportunities to impact on the drug-induced disease problem. Interventions may be proactive and include targeted education programs, system modifications to reduce error rates, or a limitation of a specific drug usage to certain units of the organization or by certain specialties.

A well-documented, complete report to MedWatch made by a health care professional is given priority review by the FDA. The toxicologist is likely to encounter a significant number of drug induced disease cases from a diagnostic and management standpoint, therefore practitioners of the specialty can make a significant impact on ADE reporting. All staff, including medical and clinical toxicologists and their trainees, should always submit an adverse event report locally for appropriate cases they encounter. Hospitals generally do not mandate or request that the reported event be “serious” as a requirement. The FDA MedWatch system requests that the reported events must be serious in nature or not previously associated with the medication involved. Other organizations that collect data on medication errors, such as the Institute for Safe Medication Practices, provide valuable insight and support to the drug safety community. They maintain a database, as do poison centers, and reporting is voluntary but important. In addition to reporting of the ADE, the medical toxicologist

should promote publication of case reports of all new adverse events or adverse events occurring with newly approved products. Such publication often stimulates appropriate reporting of ADEs from other practitioners and generally raises awareness concerning a new ADE.

An additional and very important role for toxicologists who work with poison centers is to facilitate the accurate reporting of poison center data to the National Poison Data System. Poison center data are invariably considered in the overall safety evaluation of approved and marketed drug. This is especially true for drugs with the potential for abuse and misuse. Accurate information and causality assignment for fatalities by the medical and managing directors of PCs can greatly aid regulatory decisions and guide efforts to improve drug safety at the national and international levels.

SUMMARY

- Drug-induced disease is common in both inpatient and outpatient settings.
- Despite significant advances in medical science applied to drug development and regulation, ADEs continue to occur and will continue to do so for the foreseeable future. ADEs have a significant impact on patient mortality and morbidity in addition to producing a significant burden on the health care system.
- ADEs caused by newly approved drugs and ADEs resulting from a previously unrecognized association with drugs with a long marketing history continue to be a significant cause of mortality and morbidity.
- The rapidly expanding number of approved drugs requires that the medical and clinical toxicologists and other practitioners have a continuing commitment to reduce the risk for ADEs in medical practice.
- Active participation in clinical, teaching, and administrative roles that can improve ADE detection, analysis, and accurate reporting at the local and national levels by medical and clinical toxicologists has led to important advances in patient safety.
- Maintaining a high level of commitment to these tasks as individuals and as a specialty will ultimately improve patient safety and benefit society.

MEDICATION SAFETY AND ADVERSE DRUG
EVENTS

Brenna M. Farmer

HISTORY AND EPIDEMIOLOGY

Patient safety is of great interest to many regulatory groups, such as The Joint Commission, hospital administrations, health care professionals, and the general public. The interest has continued to grow since the publications of two reports by the Institute of Medicine. The first report, in 1999, focused on all medical errors and introduced measures necessary to ensure a safer health care system.⁸⁵ The second report, in 2006, focused on reducing medication errors and adverse drug effects.⁸³ These reports and others reveal that medications errors represent up to 25% of all medical errors.⁴⁹ Many health care institutions address medication safety through their pharmacy and therapeutics (also commonly called drug and formulary), medication safety, patient safety, and quality improvement committees. Table 140–1 shows a timeline of some important developments in medication safety.

TABLE 140–1. Critical Events in the Evolution of Medication Safety

1820	United States Pharmacopoeia (USP) is established in Washington, DC
1906	The Pure Food and Drugs Act is passed by Congress
1927	The Bureau of Chemistry is re-formed into Food, Drug, and Insecticide Administration and the Bureau of Chemistry and Soils
1930	The Food, Drug, and Insecticide Administration was renamed the Food and Drug Administration (FDA)
1962	Kefauver-Harris Drug Amendments passed to ensure drug efficacy and greater drug safety President Kennedy proclaims the Consumer Bill of Rights, which includes the right to safety, right to be informed, and right to choose
1963	Representatives from FDA, USP, American Medical Association (AMA), and American Pharmacists Association form the US Adopted Names Council to establish drug nomenclature
1968	The FDA is placed in the Public Health Service after reorganization of the federal government health program
1970	The FDA requires the first patient package insert
1975	The Institute of Safe Medication Practices's (ISMP) work officially begins with a continuing column in <i>Hospital Pharmacy</i>
1987	The first ISMP list of dangerous drug abbreviations is printed in <i>Nursing '87</i>
1989	Agency for Health Care Policy and Research (AHCPR) is established as an agency in the Public Health Service in the Department of Health and Human Services
1991	Institute for Healthcare Improvement is founded as a not-for-profit organization to aid in improvement of health care quality USP and ISMP create Medication Error Reporting Program (MERP)
1993	A consolidation of several adverse reaction reporting systems is launched as MedWatch, the FDA voluntary reporting system for problems associated with medical products
1996	The National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) is formed
1997	National Patient Safety Foundation is established with patient safety as its sole purpose ISMP founds a subsidiary, Medical Error Recognition and Revision Strategies (Med. E.R.R.S.), to work with drug companies to predict problems with names, labels, and packaging
1998	USP launches MEDMARX, an Internet-accessible medication errors reporting system for hospitals Founding members of The Leapfrog Group meet to discuss ways to purchase health care to influence its quality and affordability ISMP publishes a list of high alert medications
1999	The Institute of Medicine (IOM) <i>Report To Err is Human: Building a Safer Health System</i> ¹⁷ is published The Leapfrog Group founding members establish the reduction of preventable medical errors as their initial focus The National Quality Forum is created as the President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry Agency for Health Care Policy and Research is renamed Agency for Healthcare Research and Quality
2006	IOM <i>Report Preventing Medication Errors</i> ¹⁸ is published
2007	USP and Quantros, a company that collects data on health care quality, patient safety and accreditation, partner to run MEDMARX

Studies of medical errors, including those involving medications, are of a highly variable quality and usefulness. This occurs in large part because they address diverse populations, the definitions utilized vary, and a variety of data collection techniques, including observational studies and voluntary reporting, are employed.

One study estimates that 180,000 people die each year of medical errors,⁶⁴ and 60% of these injuries are probably preventable.¹⁷ The Institute of Medicine estimates that an additional 44,000 to 98,000 people die each year from medical errors.⁸⁵ However, despite having methodologic differences, both studies establish that medical errors cause thousands of deaths each year. Studies like these illustrate the “Swiss Cheese Model of Error,”⁹² that is, multiple errors must align with an initial error to lead to harm.

More than 1.5 million preventable adverse drug events (ADEs) may occur each year.⁸³ An ADE is an untoward event or outcome associated with the use of a drug. The definition of ADEs includes medication errors as well as adverse reactions to a drug and drug interactions. A medication error is “any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer.”⁸¹ An adverse drug reaction is a sign or symptom related to use of a medication that results in unpleasant effects when an error has not occurred. An adverse drug reaction is also an ADE.⁵ Those ADEs and medication errors with serious effects lead to 3.1% to 6.2% of all hospital admissions.⁶²

In 1997, the cost of a single ADE was estimated to be \$2000 to \$5000 at academic medical centers.^{10,22,23} Similarly, in 2012, a retrospective multi-center study of community hospitals estimated an increased cost of \$3000 to overall care and increased length of stay of 3 days above expected when an ADE occurs.⁴⁶ Other studies estimated that the annual cost of ADE morbidity and mortality was greater than \$77 to 177 billion in the ambulatory care setting,^{33,50} \$2 billion in hospitals,^{10,23} and \$4 billion in nursing homes.¹⁶ These costs exclude legal or other costs that accrue to the patient or their families.

Deaths from Medication Errors and ADEs

Although medication errors are the most common cause of iatrogenic patient injury, less than 2% result in injuries. Nevertheless, the incidence of ADEs in hospitalized patients is estimated to range from 2% to 20%²² resulting in 7000 deaths annually in the United States.⁸⁵ A retrospective review of hospital death certificates by ICD 9 and ICD 10 codes from 1983 to 2004 revealed an increase of 361% in fatal medication errors and a 33% increase in deaths from ADEs occurring in a patient's home.⁹¹ The hospital death certificate review also revealed an increase in fatal medication errors 32 times higher when prescription medications were combined with alcohol and or illicit xenobiotics.⁹¹ According to voluntary MedWatch reports to the US Food and Drug Administration (FDA), 17% of reported ADEs were associated with death, 7% were associated with permanent disability, and many others had serious complications. Women and elderly patients were at the highest risk.⁷⁸

National Coordinating Council for Medication Error Reporting and Prevention Taxonomy

A useful medication error taxonomy, developed by the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP), classifies medication errors according to severity of outcome (Fig. 140–1).⁸¹ Importantly, the categories of least severity (A and B) describe circumstances or events in which the potential to cause error exists, or the error occurs but does not affect the patient. These “near misses” are so frequent that they serve as a critical source of information related to systems problems and education about medication error, but are typically underreported and underappreciated. In one study of 154,816 errors reported by hospitals and health systems to MEDMARX from 1999 to 2001, most of the errors were in category C (47%) and resulted in no patient injury, whereas there were 19 errors in category I, contributing to or resulting in patient death, comprising 0.01%.⁹⁶ See Fig. 140–2 for a comparison of errors in the inpatient versus the emergency department (ED) setting based on the NCC MERP classification.

Medications Involved

FDA reports suggest that opioid analgesics and immune modulators are the most common medications in which errors resulted in death.⁷⁸ The medications most frequently involved in errors and ADEs reported to MEDMARX were insulin, anticoagulants, morphine, and potassium chloride.⁹⁶ These medications are considered high alert drugs according to the sentinel event alert system of The Joint Commission. Recently, The Joint Commission has focused more on all opioids (not just morphine) in order to promote safe use in the hospital setting.¹⁰⁵ Identifying characteristics of high-risk drugs include low therapeutic index, pharmacokinetic interactions, inherent undesirable effects, newly approved or “off-label” use, and direct-to-consumer promotion.¹³ Table 140–2 lists medications commonly reported and their classes of errors.

TABLE 140–2. Medications or Classes Commonly Responsible for Medication Errors

Acetaminophen	Electrolyte replacement
Albuterol	Potassium chloride
Antibiotics	Fluid replacement therapies
Amoxicillin	Furosemide
Cefazolin	Insulin, other antidiabetics
Cephalexin	Opioids
Levofloxacin	Fentanyl
Penicillin	Meperidine
Vancomycin	Methadone
Anticoagulants	Morphine
Heparin	Opioid-acetaminophen combinations
Warfarin	Oxycodone
Aspirin	Sedatives
Cardiovascular	Benzodiazepines
Clopidogrel	
Digoxin	
Inotropes	
Vasopressors	
Chemotherapeutics	

The Medication Process

The Medication Process comprises the five stages in the sequence of ordering a medication to its delivery to the patient.

The stages are prescribing, transcribing, dispensing, administering, and monitoring.⁶ For patients discharged from the ED or hospital, discharge, and follow-up is the sixth stage.²⁸ Although the medicating process has only six stages, there are multiple steps within each stage. The potential for error is high, increasing proportionately as the number of steps and their complexity increase. Figure 140–3 describes typical errors that occur at each stage in the process, along with prevention strategies.

Stage	Error producing conditions	Medication error reducing strategies
Prescribing	Incomplete knowledge of medication Incomplete knowledge of patient	Readily available medication reference systems Increased pharmacist availability Take a thorough medication/medical/allergy history Physicians order entry Computerized decision support Pediatric patients: Determine accurate weight in kilograms Be alert for calculation/decimal point errors Caution with "off-label" prescribing Geriatric patients: Consider co-morbidities and drug-drug interactions in particular Consider possibility of falls with new medications Consider renal, hepatic and thyroid function Follow Beers criteria Potentially pregnant patients: Rule out pregnancy Careful evaluation of risk/benefit
Transcribing	Verbal orders Poor penmanship Abbreviations, symbols	Avoid verbal orders except in emergencies Write legibly; print if necessary Avoid acronyms or prohibited abbreviations Electronic order transcription Team communication errors Indicate decimal point clearly No trailing zeros Avoid apothecary terms Include physician phone number/pager
Dispensing	Dispensing by nurses Dispensing by physicians Patient ID	Nurses dispense to another nurse and not themselves No dispensing by physicians Automated dispensing Check with physician if any ambiguity in order Check correct placement of decimal points Check weight is correct in kilograms Always check for allergies to medication class Doubly confirm patient identification; bar-coding Double-check arithmetic
Administration	Multiplicity of medications Potency of medications Multiple patients Parenteral administration Medication incompatibilities Physician administration	Be prepared to challenge orders Clarify any ambiguity or doubt concerning medication order Consistent consultation with reference materials Consultation with hospital pharmacist if available Call back verbal orders Implement systematic safety checks Avoid physician administration of medication whenever possible
Monitoring	Potent medications Parenteral administration Emergent procedures Complex procedures	Ensure adequate monitoring technology Ensure adequate monitoring personnel Clear protocols for conscious sedation or rapid sequence intubation Ensure adequate monitoring time following drug administration
Follow-up	Patients leaving hospital or other healthcare facility, and especially medicated patients	Reconcile all medications No verbal discharge instructions to patients given amnestic drugs Provide written information on any new medication to patient if possible Advise patients of any necessary follow-up Consider effect of medication if patient driving home

FIGURE 140–3. Stages in the ordering and delivery of a medication and typical errors associated with each stage. (Based

on data from Bates DW. Using information technology to reduce rates of medication errors in hospitals. *BMJ*. 2000; 320:788–91. Peth HA. Medication errors in the emergency department: a systems approach to minimizing risk. *Emerg Med Clin North Am*. 2003;21:141–58.)

The greatest number of errors resulting in preventable ADEs (medication errors) occurs at the first prescribing stage.⁷ In a study of serious medication errors, 39% were found to occur at the prescribing stage, 12% at transcription, 11% at dispensing, and 38% at administration.⁶⁵ In one study of 17,808 inpatient and ED medication orders, 6.2% of orders written involved a prescribing error and 30% of these were likely to harm the patient if they were not discovered.¹⁵ Another recent prospective study suggests that up to 43.8% of medications orders on hospital wards had a prescribing error discovered by ward-based pharmacists, despite the level of prescriber experience.⁹⁸ In the ED, most errors occurred in either the prescribing or administration phase.⁸⁹

Transcribing errors usually involve poor communication due to illegible handwriting, the use of trailing zeroes, or inappropriate abbreviations. Poor handwriting can also lead to confusion, particularly with regard to look-alike and sound-alike medications.⁹⁰ All information, whether printed, spoken, or otherwise communicated, must be transmitted in a clear, unambiguous, and timely fashion with avoidance of abbreviations. In its 2004 National Patient Safety Goals, The Joint Commission developed a minimum list of five sets of dangerous abbreviations, acronyms, and symbols that should not be used, and proposed preferred terms.¹⁰⁴ The Institute for Safe Medication Practices (ISMP) also published a comprehensive list.⁴⁸ By not using these abbreviations, the hope is that communication will be improved and that there will be no misinterpretation of poor physician handwriting.

Dispensing errors are most commonly due to substitution and labeling errors.⁹⁹ Errors at the stage of administering medications include incorrect drug, incorrect dose, incorrect route, and a drug given to the wrong patient. Computerized provider order entry (CPOE) was introduced to improve the medication process from prescribing to administering but has introduced new problems. See the Information Technology section for further discussion.

Monitoring and discharging with follow up are associated with fewer errors. This phase involves attention to liver and kidney function, checking xenobiotic concentrations, and attention to and evaluation of drug interactions and pharmacokinetic interactions.²⁸ Monitoring must be an ongoing process that begins when the patient receives the medication, regardless of where the patient is in the health care system, and continues as long as the individual continues to have the medication prescribed. In the acute stages of treatment, such as in the hospital or ED, the process is especially important and requires optimal three-way linkage between the pharmacy, laboratory, and physician.⁹⁷ This process must be maintained throughout the individual's continued relationship with the health care system. In the outpatient setting, providers must be aware of signs and symptoms related to adverse drug effects while they are monitoring and following up patients. In a study of 661 patients in four primary care practices, patient reports of medication side effects to their physicians led to changed therapies in 76% of cases. A failure to identify medication-related symptoms and change therapy resulted in 21% ameliorable and 2% preventable ADEs. Ameliorable ADEs were defined as those in which "the severity or duration could have been reduced substantially had different actions been taken."¹¹²

SPECIAL AT-RISK POPULATIONS

Important medication safety issues exist for children and older adults, a problem that is exacerbated by their underrepresentation or exclusion from clinical trials. It is estimated, for example, that only a third of the medications used to treat children have been adequately tested in this population.²⁵ Similar concerns apply to medications used in older adults and those individuals with specific underlying medical conditions that would have excluded them from trials.⁴⁷

Pediatric Considerations

Pediatric adverse events involving medications may occur from the prenatal period and throughout childhood from the neonatal period through maturation. Errors may occur in all settings: the home, in ambulatory care, the ED, hospital floor, pediatric intensive care unit (PICU), and neonatal intensive care unit (NICU), and by all caregivers. Approximately 1 in 6.4 pediatric orders results in an error that reaches the child.⁷² Because of the greater need for dose calculations to allow for weight-based dosing, dose-related errors are more likely to occur in children.⁵² Errors also occur in the home environment with nonprescription medications, but the true incidence is unknown. In one survey, the errors associated with home antipyretic use were estimated at almost 50%.⁷³ These errors were typically associated with underdosing, which is generally of little immediate harm.⁹⁵ In the ambulatory care setting, the incidence is unknown but one study identified "numerous" errors in prescription writing in a pediatric clinic.¹¹⁰ In the ED setting, the error rate was estimated at 10% of all pediatric charts.⁵⁷ There may be an increased risk of errors in children cared for in nonacademic or rural EDs compared with academic or pediatric EDs.⁵⁵ A retrospective chart review of 177 pediatric charts in four rural EDs identified 84 different medication errors in 69 of the 135 patients who received medications. The outcomes of these errors were in NCC

MERP categories A to D (Fig. 140–1).⁷¹ A study of 18 pediatric ED voluntary event/incident reporting data showed that 19% of all incidents were related to medication events. A total of 94% were medication errors and 6% were ADRs. Errors included using incorrect weights, duplicate dosing, and miscalculations. Human factors contributed to 84% of the medication errors in this study.¹⁰⁰ See the Factors Affecting Human Performance section for further discussion.

Hospitalized children experience up to three times the rate of medication errors and potential ADEs as do adults.⁵³ The incidence of medication errors of hospitalized children is estimated at about 6% for all orders written; the majority (74%) of these occur at the prescribing stage and approximately 20% are classified as potentially harmful based on a 4-point Likert scale developed by the researchers instead of the NCC MERP classification previously described.³⁸ Pharmacists based on pediatric hospital wards, discovered that 5.9% of orders contained a prescribing error and were able to intervene through the order entry system.³⁰ Generally, children in the intensive care unit appear to be at higher risk for errors compared to adults and hospitalized children not in the ICU, presumably reflecting the increased complexity of disease and the medications used.⁵⁵ Incorrect dosing, especially with the intravenous route, is the most commonly reported error. Dosing of antimicrobials and intravenous fluids are the most common medications involved.^{29,36,53} Errors and discrepancies found in hospital discharge instructions, with lack of complete medication reconciliation, could lead to patient harm⁵¹ (Chap. 32).

Geriatric Considerations

Medication errors in older adults also occur throughout the health care continuum: the home, ambulatory care, in nursing homes, in the assisted-living setting, and in the hospital (Chap. 33). Adults older than 65 years of age have a relative risk of 2.37 for drug complications and 4.12 for medication errors compared to adult patients younger than 65 years of age.¹⁷ The incidence of medication error at home with nonprescription medications is unknown but, for reasons outlined below, would be expected to exceed that of the younger adult population. Using a variety of methodologies, ADEs were evaluated for a 12 month period in a multispecialty ambulatory care practice in a cohort of 27,617 Medicare enrollees, equivalent to more than 30,000 person-years of observation. Extrapolating their findings, to the estimated 38 million Medicare enrollees (those ≤ 65 years), would predict nearly 2 million ADEs annually, of which more than 25% would be considered preventable and about 180,000 fatal or life threatening.⁴³ A recent study estimates that there are about 265,802 ED visits in patients older than 65 years of age for ADEs and 99,628 of these patients require admission to the hospital. In the same study, patients older than 80 years of age constituted half of those admitted to the hospital. Medications or classes of medications involved in two-thirds of the hospitalizations were diabetic and antithrombotic medications.¹⁹

There are more than 1.5 million nursing home residents in the United States. The average such resident uses six different medications, and 20% use ten or more.¹⁴ Extrapolating the findings of a study of 18 community-based nursing homes in Massachusetts over a 1 year period predicts 350,000 ADEs annually, more than one-half of which would be preventable.⁴² Fatal or life-threatening ADEs would represent 20,000 of these predicted events of which 80% would be preventable. Approximately one million other seniors live in assisted-living facilities, and are vulnerable to medication errors for a variety of reasons, including inadequate physician support, inadequately trained staff, and staffing shortages. ADEs cause 10.5% of hospital admissions for geriatric patients and are the most common type of adverse event occurring in hospitalized elderly patients.^{66,114} These drugs result in nearly 50% of ADE-related visits to the ED but are only prescribed during 9.4% of outpatient visits.²⁰

Addressing these issues is becoming ever more important as the US Census Bureau predicts a rise of 62 million in the number of Americans 65 years of age or older by the year 2025 and a 68% increase in the 85 years of age or older population that may be at an even higher risk.⁴ Advancing age brings with it several important considerations from the point of view of medication safety. Medical comorbidity increases with age, and therefore an increasing likelihood of receiving multiple medications. With more medications, the number of potential errors and interactions increases. Frailty and cognitive decline in older adults may result in errors following self-administration. Alterations in medication absorption, metabolism, distribution, and elimination may all affect the efficacy of the medication (Chaps. 9 and 33).

Criteria were developed in both the United States (Beers)^{11,12,35} and Canada⁷⁴ to determine appropriateness of medication prescribing for nursing home residents. Forty eight medications or classes of medications to avoid, and medications to avoid in the presence of 20 diseases/conditions were identified.³⁵ The prevalence of inappropriate medication use in older adults is estimated to be in the 12% to 40% range.¹⁰² One in five prescriptions given to elderly individuals are considered inappropriate based on Beers criteria, with diphenhydramine and amitriptyline being the most common medications prescribed inappropriately.⁸⁷ Older adult patients medicated with benzodiazepines, for example, have a four-fold increase in falls (Chap. 33).

RESPONSE TO MEDICATION ERROR

One of the leading causes of medication errors is human performance deficit. Almost invariably a human action will

precede the ADE, and this temporal contiguity of action and consequence typically generates a tendency to blame someone. In most cases the blame will fall on the last person to have had contact with the patient. In recent years, however, a consensus has emerged that blaming people for errors is counterproductive. The number of ADEs that result from egregious behavior is very small, and more often than not an explanation for the fault will be found within the system that allowed the error to occur. Attempts to understand the nature of these faults, and to correct them, while being sensitive to the potential for unintended consequences, is the most appropriate response. Several processes can be used to respond to errors or system-problems. These include root cause analysis, clinical incident analysis, failure mode and effect analysis, and Lean Six Sigma (LSS).

Root cause analysis (RCA), a term originally used to investigate major industrial events, is a technique that provides a structured, process-oriented analysis of sentinel events. The Joint Commission in accredited hospitals mandated its use in 1997. It is a time-consuming process requiring multidisciplinary teams with specialized training, and is subject to bias and methodologic limitations.¹⁰⁸ Nevertheless, a judiciously conducted RCA may provide insights into systemic failures underlying the ADE, and identify areas that require change. An alternative approach, a clinical incident analysis protocol, was developed that more appropriately shifts the emphasis from the individual to the system.¹⁰⁷ The clinical incident analysis protocol utilizes seven factors as the basis for an investigation. Some organizations have developed a hybrid combining these two approaches. Both RCA and clinical incident analysis are conducted retrospectively, and therefore subject to retrospective bias

An alternative approach is failure mode and effect analysis (FMEA), which proactively attempts to identify potential errors, to initiate preventive measures. A multidisciplinary group is utilized in the FMEA approach to identify a process or subprocess that needs analysis, to identify the steps of the process and determine the risk/likelihood/severity of failure of each step. Once this phase is accomplished, the team prioritizes a high-risk step and conducts an RCA to make recommendations on redesigning the step. The establishment modifications are analyzed in their performance to determine change and decrease in risk. This process is designed as a quality control and assurance to protect the proceedings from legal investigation.³

Other processes are being introduced into the health care industry to improve quality of care and safety and reduce costs. Two such approaches are Lean and Six Sigma, sometimes utilized together as LSS. Both were initially described in the Toyota Production System and have been adapted to health care. Define, measure, analyze, improve, and control are all steps related to LSS. It involves defining the process that needs evaluation, determining how to measure the process, analyzing the data collected based on the determined measures, forming an improvement plan based on the analysis, and putting a new process in place with the goals of developing a lasting culture regarding the newly improved process with elimination of waste.^{1,116} Each of these steps has principles to guide the use of LSS. The Agency for Healthcare Research and Quality has made specific forms to aid health care facilities when adopting these approaches to safety and improvement.⁶³

REDUCING ERRORS

To reduce medication errors, each hospital should simplify, standardize, and stratify processes and communication. The medication process should be carefully automated with computer order entry and bar coding as extensively as the system will permit. While these information technology solutions will aid the medication process, nothing is perfect and each change introduces new problems. See the Information Technology section later. Limitations of attention and vigilance should be understood and the reporting of errors in a nonpunitive environment should be encouraged.⁶⁵ Improving information access, error proofing, reducing reliance on memory, enhanced training, and the use of buffers or redundancy in an attempt to prevent errors should also be encouraged.⁶⁴ Each time a medication is given, the focus should be “right drug, right dose, right route, right patient, at the right time.”

In 2003, the American Academy of Pediatrics Committees on Drugs and on Hospital Care developed a position statement regarding the reduction of medication errors in the pediatric population. The recommendations can be adapted to all hospital settings and to patients of all ages. These recommendations include appropriate staffing, utilization of the resources in the pharmacy, standardization of hospital equipment and protocols, and the development of a nonpunitive, barrier-free system to report and easily track errors.¹⁰³ Other more recent groups also encourage reduction of medication errors and participation in medication safety. The American College of Medical Toxicology encourages medical toxicologists to use their expertise and training to aid health care systems in reduction of errors and other pharmacy and therapeutics issues.²

For older adults, prescribers should review medication indications and avoid age bias. Polypharmacy should be limited, with medications prescribed only as necessary. Dosing should be adjusted, as needed based on renal and hepatic function. Medication review by pharmacists can aid in decreasing the use of potentially inappropriate medications and in decreasing the number of medications prescribed (polypharmacy).⁷⁶ In the hospital, outside of the emergency department and emergent situations, pharmacists review all medication orders, when available, and verify the medication as

appropriate prior to it being dispensed. Pharmacists can also aid in medication reconciliation at transitions of care and upon hospital discharge to prevent complications of polypharmacy.^{40,59}

FACTORS AFFECTING HUMAN PERFORMANCE

Human factors lead to many medication errors. In fact, it is not surprising that human performance deficits are the primary causes of medication errors in such an extremely complex medical environment. A performance deficit means that the individual making the error had the prerequisite knowledge to avoid the error but failed to do so. There are numerous variables that contribute to performance deficit, including many ergonomic issues such as workload, distractions, resource limitations, and staff shortages. This environment is both burdened and enriched by many inherited properties. Human factors and ergonomics theory draws on a variety of disciplines, including industrial engineering, industrial psychology, cognitive psychology, and information technology. Much can be done to optimize the interface between humans and the work environment and to ensure that systems operate more efficiently. As a general principle, it would be preferable if the dominant purpose in designing medical devices and processes was that they fit human users, and not the converse. Table 140–3 lists some of the more common human performance deficits. Such errors often manifest as simple slips of action, or execution failures, arising from distraction by something other than the task at hand.⁹² Vigilance is better maintained in individuals who are well rested and working without interruption or distraction in a well-designed environment. Fewer medication errors occur in optimally designed environments.⁶⁵

TABLE 140–3. Common Factors That May Adversely Affect Human Performance ^{27,96}	
Attentional capture	
Diminished motivation/morale	
Distractions	
Fatigue	
Fragmentation, transitions of care	
Inadequate resource availability (Resource Availability Continuous Quality Improvement	
Trade-Off)	
Increased work acuity/cognitive load	
Inexperience	
Interruptions	
Poor workplace ergonomics	
Sleep deprivation/debt	

Human performance deficits such as diminished memory, sleep deprivation, depression, and distractions contribute to errors. Resident physician mood and lack of sleep are also factors in performance deficits. Depressed residents made 6.2 times as many medication errors as nondepressed residents.³⁴ Sleep deprivation and improper supervision were highlighted initially after the Libby Zion case, in which a patient on phenelzine developed fatal serotonin toxicity following the administration of meperidine by a sleep-deprived and inadequately supervised intern. Interns working a traditional schedule of call every third night with extended work shifts (36 hours) made 35.9% more serious medical errors than those with the current reduced work schedule.⁶⁰ In particular, there were 20.8% more serious medication errors during the older work schedules compared with the current reduced hour schedule.⁶⁰ In 2008, an Institute of Medicine study addressed resident work hours and patient safety. This report recommended residents be provided with designated sleep time during each day and rest periods each week in order to decrease the risk of fatigue-related medical errors.⁸⁴

A particularly important goal for human performance deficit is the reduction of cognitive load and distractions. Many medication errors originate from cognitive failings because of interruptions, distractions, inexperience, or simple overloading—referred to as performance deficit. In the ED, increased cognitive load such as related to increased number of boarding patients, increased number of medication orders, and increased number of medications to be administered all lead to increased medication errors.⁸⁹ Further efforts must be directed at strategies to reduce cognitive failure. The adoption of some very simple strategies based on human factors engineering principles will reduce error, such as simplification of the number of steps involved, reducing reliance on memory, applying cognitive forcing strategies,²⁷ and using cognitive aids. Research into reducing distractions during medication administration has focused on adapting principles from the airline industry, “the sterile cockpit principle.”³⁷ This principle limits interruptions and distractions that could interfere with proper performance of a critical task or tasks. In the airline industry, the use of this principle occurs during takeoff, taxi, and landing. In medication administration, this principle involves the use of “do not disturb” signs or vests worn by the nurse administering medications, no conversations to disrupt the medication nurse during this important task, and the other nurses on the unit answering phone calls or patient/family questions. This approach reduces medication

administration errors by improving human performance.^{37,93} One particularly useful aid to reduce cognitive load is the color-coded Broselow-Luten system, for pediatric medication dosing.⁶⁹ This approach has the potential for further development to improve the safety of nonprescription medications and other potentially dangerous products used in the home.

Another factor that contributes to errors is the assignment of a new role to a provider such as asking physicians to dispense or administer medications. Pharmacists are the only professional group formally trained and experienced in dispensing medication, and not surprisingly, their presence is associated with a lower medication-dispensing error rate.^{58,67} Nurses administer medications because they receive such training and the administration should be restricted to them except during specific circumstances such as procedural sedation.²⁸

KNOWLEDGE DEFICITS

The two most common factors contributing to prescribing errors are related to knowledge deficits. These deficits include lack of knowledge about the drug and about the patient.^{65,68} Knowledge deficits about medications are likely due to the number new medications, dosage formulations, and indications. With the large number of medications prescribed and the continuing and frequent release of new medications, it is difficult to know all of the relevant clinical pharmacology of each medication, including interactions, side effects, and contraindications. Decision support, most commonly in electronic format, should be contemporaneously available to health care professionals to assist in decreasing prescribing errors.⁹⁰ However, electronic pharmacopeias, as a form of decision support, can have errors and omit warnings, such as recently discussed with extended-release or long-acting opioids.⁶¹

Knowledge deficits may also affect dosing calculations and drug ordering. This may be related in part to the lack of formal education regarding the medication process during medical school training. Only 10% of medical students answered dose calculation questions correctly.¹¹³ However, students in their final year of training performed much better than students in the lower years.¹¹³ It is unclear where, when, and how the students obtained the knowledge in the higher years. Specific training is needed in both of these areas of calculation and order writing. Improvements have been demonstrated following a short educational intervention,⁸⁶ but it is unclear how long this knowledge is retained. Generally, there appears to be a tacit assumption that these skills will be acquired during clinical training, but this study suggested that this knowledge might not be acquired independently and that specific training is indicated.

The prevailing emphasis in physician training is on knowledge acquisition. Less time is spent inculcating critical thinking skills and/or teaching reasoning, the assumption being made that these are passively acquired during the process of training. Although this is partially true, it does not exclude opportunities to improve these cognitive faculties by direct intervention.²⁶

COMMUNICATION

Improved team communication should result in fewer medication errors. Orders should be written clearly, or CPOE (discussed in detail in the Information Technology section) should be used. Orders should optimally include the indications for the medication. Both generic and trade names should be included in orders so that confusion with look-alike/sound-alike drugs may be avoided. Abbreviations should have limited use and trailing zeros should be eliminated. Verbal orders should be used sparingly due to the high risk of sound-alike medications and confusion with dosing.⁹⁰ If a verbal order is necessary, then it should be restated immediately to the ordering clinician to ensure that it is correct and restated from the physician to the nurse in a “closed loop” communication process.

Communication theory should receive more emphasis in health care training. Good communication skills both within and among disciplines and especially between practitioners and their patients will limit errors. As patients are admitted, transferred within, and discharged from health care facilities, it is essential that precise communication as to what medications, strengths, and doses the patient is receiving occur. This process is known as medication reconciliation. Any changes that have occurred must be accurately recorded. This effort was adopted by The Joint Commission in 2005 and continues to be an important National Patient Safety Goal. As with other aspects of patient safety, these issues should be formally introduced into the education curriculum. Studies have shown that pharmacists are an integral part of optimal medication reconciliation.^{40,59}

INFORMATION TECHNOLOGY

Information technology (IT) in health care has been ponderously slow to develop compared with its use in other organizations, but it is now gathering momentum and has obvious potential to improve patient safety.^{8,82} On the other hand, as considerable gains may be made, new technology can also be expected to introduce new types of errors.^{21,115} The US

Pharmacopeia announced in 2004 that nearly 20% of 235,159 medication errors reported to MEDMARX involved computerization or automation.⁹⁶ One study evaluating CPOE in a tertiary care hospital found that the system actually facilitated a wide variety of medication error risks.⁴⁴ Common errors associated with order entry include wrong medication selection and input of incorrect data (patient weight, creatinine clearance).¹⁰⁶ Another study identified 24 different types of failures associated with CPOE but suggested that many could be easily corrected, in particular by concentrating on organizational factors.⁵⁶ However, more detailed insights have been offered into why process-supporting IT systems fail.¹¹¹ Much of the data involved in the medication process are relatively straightforward, amenable to rapid and efficient processing, including crosschecking with patient medication history and evaluating for drug interactions (an example of decision support). A study reviewing 28 trials of point-of-care decision support report showed a 4.2% improvement in patient care with a trend toward better improvement in care when a response was required from prescriber¹⁰¹

Past studies demonstrate that computerized order entry with decision support reduces the incidence of serious medication errors by 50% to 55% once the transitional instability has passed.^{9,70} This approach mainly reduces errors at the prescribing stage of the medication process and, while likely to prevent 80% of prescribing errors that led to no patient harm, the errors most likely to cause patient harm may not be as amenable to reduction as these errors may be related to dispensing, administration, or monitoring.¹⁵

In high-risk populations, CPOE reduces medication errors. In children, CPOE with substantive decision support reduced ADEs (including medication errors) and potential ADEs in an inpatient pediatrics ward.⁴⁵ It also decreased the rate of nonintercepted medication errors by 7% although there was no change in the rate of patient harm.^{53,109} In the NICU, CPOE eliminated all calculation errors as decision support included an automatic dosage calculator.²⁴ However, these decisions support systems cannot improve human errors due to entering incorrect weights, incorrect units of weight (kilograms versus pounds), or medications entered on the wrong patient.¹⁰⁶ In geriatric medication errors, CPOE resulted in less potentially inappropriate medication prescribing through decision alerts, which led to a pharmacist call to the prescriber that offered alternative choices of medications if possible.⁷⁷ Decision support in CPOE can also lead to too many alerts when orders are placed, causing alert fatigue and resulting in providers entering an answer to proceed past (or “blow-by”) the alert without reading or comprehending the alert. A study reviewing an alert about critical drug–drug interactions with warfarin found that only 19% of providers and 9.7% of pharmacists responding appropriately to the alert and changed the medication order.⁷⁵

Use of barcoding for dispensing and administration of medication ensures that the correct drug is given to the intended patient at the dose intended. Barcoding significantly decreased the relative risk of targeted, preventable ADEs by 47% to 50% in an NICU.⁸⁰ The risk of opioid related ADEs were also reduced when barcode medication administration was implemented.⁷⁹ This technique decreases the amount of time nurses spend administering medications in the ICU, allowing them to reallocate that time to other direct patient care activities.³¹ As with all technology, new problems arise with the implementation of barcoding and can lead to errors. Such problems range from inability of the scanner to read the barcode on the medication or on the patient identification band, downtime processes, mismatch of barcodes due to new manufacturer barcode, or new or aging scanners, and many more.³²

Unit dose dispensing systems, usually in association with CPOE and barcoding of medications, reduced monthly errors from five to none in the inpatient setting.³⁹ The package sent from pharmacy is prepared to administer to a specific patient at the appropriate dose, eliminating the need for the nurse to draw up medications resulting in fewer errors. Other dispensing systems, like automated dispensing cabinets (ADCs), have also been linked to CPOE, barcoding, and can allow for a pharmacist to verify correct drug, correct dose, patient allergies, and use of the medication prior to a drug being dispensed from the cabinet. These ADCs can decrease dispensing errors. However, errors can occur when using ADCs. One such problem, “drug override,” can occur, particularly in an emergency situation or as a work-around. This allows a drug to be dispensed prior to pharmacist verification. Another error, look-alike medication errors, can occur due to the small screens on the ADCs. Errors have also been known to occur when the ADCs are stocked such that an incorrect drug is placed in an incorrect bin of the ADC.⁴¹

SERVICE-BASED CLINICAL PHARMACISTS

Clinical pharmacists are now employed in high risk areas such as the ICUs, the pediatrics services, and EDs to identify and prevent medication errors. In one ICU study, the input of a clinical pharmacist during rounds saved an estimated \$270,000 annually in costs of rehospitalization due to ADEs.⁶⁷ The involvement of a clinical pharmacist in work rounds of an adult ICU reduced preventable ADEs by 66%.⁶⁷ The introduction of clinical pharmacists in pediatric services is credited with a 94% reduction of potential ADEs and medication errors.⁵³ In particular, the addition of pharmacists in the PICUs reduced the serious medication error rate by 80%.⁵⁴ One study showed that pharmacists in three EDs identified 2200 interventions with an estimated savings of \$488,000. This savings came from lower-cost medications, reduced length of stay, and fewer

readmissions.⁹⁴ Another study showed that there were 16 errors per 100 medication orders in the control group (without a pharmacist), while the intervention group (pharmacist present in the ED) only had five errors per 100 medication orders, resulting in a 67% reduction.¹⁸ A recent study suggests that the availability of ED pharmacists has even more impact on reducing errors by their assistance for questions, discussion, and consultation rather than in the review of medication orders.⁸⁸ And, as previously discussed, hospital pharmacists have been able to improve medication reconciliation across the continuum of care for patients.⁵⁹

However, fiscal restrictions will inevitably mitigate against the expansion of service pharmacists as cost-benefit arguments will be applied. An unintended consequence of having a clinical pharmacist present may be that nurses, residents, and attending physicians will always defer to them and consequently spend less time developing and maintaining their own skills for off-hour periods when such help may not be available.

ROLE OF THE TOXICOLOGIST

Clinical and medical toxicologists are in a unique position to investigate causes and help decrease the incidence of both medication errors and ADEs in the institutions where they work. With their specialized knowledge and training in pharmacology, poisoning, and clinical medicine, both physicians and pharmacists with advanced training in toxicology can also aid in the prediction, identification, and management of ADEs. Medical toxicologists should optimally be involved in Pharmacy and Therapeutics and Medication Safety committees (or related efforts) at their institutions. They should educate the providers at their hospitals as to means to reduce errors and encourage diligent reporting of medication errors to the hospital and the national databases such as MedWatch at the FDA. They should also encourage drug manufacturers to be diligent in alerting physicians with regard to identified problems.²

SUMMARY

- Medications are the principal commerce of modern medicine, and medication safety is of paramount importance to health care systems. The delivery of medications safely to patients is a complex process and is particularly important in pediatrics and geriatrics.
- Health care professionals should be aware as to why errors occur and how they can be prevented in order to improve patient and medication safety.
- Information technology holds promise for significant improvement in medication safety. Focus should be on CPOE, barcoding, unit dose dispensing, avoidance of look-alike/sound-alike medications, and education.
- Use of clinical pharmacists and updated electronic-based literature should be encouraged.
- Communication and nonpunitive local and national reporting must be encouraged in order to learn from errors.
- Patient safety requires a collaborative effort particularly with the medication manufacturer, but also with federal regulation authorities, independent research organizations, error theorists, hospital administrators and managers, information technologists, nurses, cognitive psychologists, human factors ergonomists, and chronobiologists and all of the health care professionals involved in patient care.
- Clinical and medical toxicologists have a significant role in medication safety.

141 RISK MANAGEMENT AND LEGAL PRINCIPLES

Barbara M. Kirrane and Dainius A. Drukteinis

The number and diversity of toxicologic emergencies faced by emergency department (ED) staff have increased steadily since the early 1970s and continue to rise today. This chapter discusses the medical–legal management of patients who are exposed to xenobiotics that may alter their ability to think. It also addresses the legal and ethical dilemmas routinely encountered by emergency medicine practitioners.

Patients with toxicologic emergencies require immediate care, and yet are often unable to give consent because their impaired consciousness prevents them from making informed decisions. Treating patients who present with an acute organic impairment manifested by confusion, irrational thought, or even dangerous behavior is very challenging. Emergency practitioners must recognize the medical–legal problems created when the impaired patient refuses treatment and insists on leaving against medical advice. The issue is further complicated by the variations in relevant state laws. Emergency practitioners must become familiar with the legal requirements of informed consent and the essential management necessary to avoid liability for negligence and abandonment within the state that they practice. Of particular concern are the risk management and liability issues that relate to impaired patients attempting to leave the ED before medical care is complete. The legal requirements of informed consent in emergency settings, the duty to treat, medical malpractice, battery, and negligence, are examined here. Guidelines based on generally accepted common law principles are suggested for developing appropriate patient care plans and departmental policies. These issues and principles are best illustrated by case examples.

INFORMED CONSENT

Patient 1

An 18 year-old college student was brought by ambulance to the ED after a friend reported seeing her in the bathroom with slit wrists and an empty bottle of acetaminophen (APAP). In the ED, the patient was alert and oriented to person, place, and time. Vital signs were: blood pressure, 120/65 mm Hg; pulse, 95 beats/min; respiratory rate, 16 breaths/min; and temperature, 99.1°F (37.3°C). A rapid bedside glucose concentration was 120 mg/dL. The patient stated that she ingested the APAP approximately 5 hours earlier. The health care team wished to measure an APAP concentration to determine whether N-acetylcysteine should be administered. The patient refused venipuncture and stated that she would refuse any medications. The physicians informed the patient that she might suffer irreparable damage to her liver and possibly die if not treated immediately.

Medically treating patients against their will poses a difficult problem. Forcible treatment violates a patient's autonomy and their right to privacy. However, harm may be caused to the patient if the appropriate evaluation and treatment is not performed. As an example, in the case above, the patient gives a history of ingesting a large amount of APAP, which may cause hepatotoxicity and even death if not treated ([Chap. 35](#)). Her refusal for this evaluation highlights the important issue of whether a physician is ever justified in performing an assessment of someone who is alert and oriented, yet poisoned, and who refuses treatment. Do most patients suffering from a mental illness such as depression need to be treated against their will? If the harm that faces the patient is not immediate, but certain in the near future, does the physician have the authority to treat? General principles of patient autonomy and informed consent will be elucidated here.

A patient's right to choose the course of medical treatment was first recognized in the early twentieth century in a landmark case decided by the New York State (NYS) Court of Appeals in *Schloendorff v Society of New York Hospital*.²⁴ Mary Schloendorff was admitted for abdominal pain and was found to have a mass on physical examination. Her physicians offered her a more thorough examination under anesthesia and the option for surgery. Although she consented only to the exploratory surgery, during the procedure the mass was removed. Postoperatively, Schloendorff developed an infection and gangrene, and several fingers were amputated. She sued the hospital. In its decision, the Court upheld Schloendorff's right to self-determination, and the right to refuse treatment. It stated:

Every human being of adult years and sound mind has a right to determine what shall be done with his own body and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency in which the patient is unconscious and it is necessary to

operate before consent can be obtained.²⁴

This decision became the foundation for the “Doctrine of Informed Consent.” Informed consent serves to protect a patient’s autonomy, and creates the concept that each individual has the right to choose a personal course of medical treatment.³⁶ This includes the right to refuse care, and the right to terminate care already in process. In a nonemergent situation, it is the responsibility of the physician to obtain approval from the patient or surrogate before rendering treatment.

Generally accepted components to the informed consent process consist of (1) an explanation of the treatment or procedure, (2) alternative choices to the proposed intervention, and (3) relevant risks, benefits, and uncertainties associated with each alternative. This discussion must take place whether the patient is consenting to a procedure, or refusing a recommended procedure. A patient does not automatically assume the risks of rejecting the recommendations of the physician if the patient has not been fully apprised of the consequences of his or her decision.²⁹ Furthermore, it is the duty of the physician to assess how well the patient understands the above information. Before a physician may accept a patient’s approval or refusal of care, the patient must demonstrate adequate understanding of the information discussed.

State courts may apply one of two standards to determine if the information communicated by the physician was sufficient. The reasonable person standard requires a physician to disclose information that a reasonable person in the same position as the patient would need to make an informed decision.¹⁰ The alternative is the reasonable physician standard, which requires a physician to reveal information that a reasonable physician in a similar circumstance would disclose.¹⁰ States vary on which standard they apply.

Courts recognize that the requirement for informed consent is not absolute, and that there are exceptions in which a physician does not need to obtain permission before rendering treatment. In *Schloendorff v. Society of New York Hospital*, the Court recognized that consent is not required in emergency situations. Situations are generally considered emergent if care of the patient would be compromised if there were a delay in treatment. In New York, an emergency is defined as a situation that includes both the immediate endangerment of life or health and the need for the immediate alleviation of pain.²⁷ Physicians need to determine the specific requirements of informed consent in their respective states.

Often well-intended efforts of the physician to communicate treatment information to an impaired patient prove ineffectual and present the practitioner with a medical–legal dilemma. The physician may be unable to discuss in a meaningful way the implications of the proposed treatment with the patient. Nevertheless, there is a duty to treat the patient who presents with a life-threatening condition or the potential for permanent disability. In these situations, consent is considered to be implied, and emergent treatment should be provided. The principle of implied consent is a general tenet of tort law.²¹

Risk Management Consideration and Documentation

Patient 2

A 28 year-old woman was brought to the ED by police who believed she might be a “body stuffer” (an individual who swallows drugs to avoid arrest and prosecution). The triage nurse helped the patient onto a stretcher and brought her to the treatment area and recorded normal vital signs. The patient became combative and uncooperative as the physician initiated the examination and he verbally ordered that the patient be restrained. The patient was given 40% oxygen via face mask, cardiac monitoring was begun, and an intravenous line was started with 0.9% sodium chloride at 125 mL/h, then a bolus of 100 mL of D₅W and 100 mg of thiamine were administered intravenously (IV). Orogastric lavage was then performed, and 50 g of activated charcoal (AC) was administered.

One hour after arrival the patient’s vital signs were: blood pressure, 120/70 mm Hg; pulse, 82 beats/min; and respiratory, rate 24 breaths/min. The patient was noted to be stable and transferred to an observation unit. Oxygen and cardiac monitoring were discontinued. No further orders were: written, and the patient remained restrained. Three hours later the vital signs were: blood pressure, 110/60 mm Hg; pulse, 92 beats/min; and respiratory rate, 18 breaths/min. A nursing note stated the patient was resting comfortably.

Forty-five minutes later, the initial physician completed his shift at midnight and informed his replacement that the patient was stable and resting in the holding area.

At 4:20 am the patient was found unresponsive and hypotensive, with agonal respirations and a weakly palpable pulse. She felt very hot to the touch and had a rectal temperature of 108°F (42.4°C). Resuscitative efforts were initiated but were unsuccessful. Thirty minutes later the patient was pronounced dead.

Several important risk management questions frequently arise in medical malpractice litigation involving the ED. To prove that a case constitutes medical malpractice, a plaintiff’s attorney must show clear and convincing evidence of a departure from good practice by the physician. The attorney must further demonstrate that the negligent act or omission by the physician proximately caused the patient’s injury. Courts have held that where “there is substantial probability that the [defendant physician’s] negligent conduct caused the resulting injury, that sufficient evidence has been developed against [the] physician.”³⁵

The problems associated with an improperly documented ED record are numerous, but they can be minimized if the practitioner is cognizant of risk management principles. When the attorney for the patient (plaintiff's attorney) introduces evidence to prove the case, the central document in the medical malpractice trial is likely to be the ED record. Thus, every entry in that record is scrutinized with great care by both parties (plaintiff and defendants), and the importance of completing it with knowledge of risk management implications should be a concern for all health care professionals.

The physician is required to write a medical record that will amply support the basis for the medical judgments exercised. When a physician chooses to write only a summary statement on the record without noting supporting clinical data or patient history, claims alleging failure to diagnose will be extremely difficult, if not impossible, to defend. One of the basic elements of the defense in a medical malpractice case is that the physician's judgment was appropriate, given the clinical facts and the patient's history available at that time. Therefore, physicians who do not record supporting clinical data and history deprive themselves of a strong "medical judgment" defense.

Inappropriate entries or markings on the medical record can weaken the defense in a liability case. For example, in attempting to correct an error in entering a PO₂ value, if the physician or nurse totally obliterates the number, an attorney representing a patient may suggest to the jury that the obliteration was done intentionally to conceal clinical data harmful to the position of the defense. If a physician must correct a prior entry made on the record, then the preferable method is to draw a single line through the value or word to be changed, insert the correct information directly above, and initial the correction. Timing and dating the correction also precludes potentially difficult questions of chronology and responsibility in a courtroom setting. By following these suggestions, the physician can avoid any accusations of intentionally concealing an error in judgment (Fig. 141-1).

Preferable				Unacceptable			
Example 1				Example 2			
ABG #1	pH	7.31		ABG #2	pH	7.31	
PCO ₂	45			PCO ₂	45		
PO ₂	38	58 md	4/22/94	PO ₂			

FIGURE 141-1. Examples of the preferred and an unacceptable procedure for correcting an error in the medical record.

A frequent claim is that the patient was abandoned or improperly monitored. For the above patient, although the chart appears to document repeated vital signs at appropriate intervals, no temperature is included after the first set until the patient is moribund, nor is any mention made again of the continued use of restraints, the continued need for these restraints, or any adverse effects developing from the use of restraints. Additionally, documentation of physician assessment of the patient's medical condition is incomplete. For example, there is no mention in the physician's notes of the possible cause of the patient's change in mental status. Likewise, there is no documentation regarding the police officers' concerns that the patient was a "body stuffer." Body stuffers quickly ingest a drug to avoid detection, which can result in life-threatening toxicity (SC 5). Documentation of the physician's review of this concern is necessary.

Quality assurance reviews of ED records often demonstrate inadequate charting by physicians and nurses monitoring patients who remain in the department for prolonged periods of time. Under any circumstances, a lapse of documentation of the patient's clinical condition for 4 hours or more after the initial physician and nursing assessment creates a potential risk management problem. In a lawsuit, the plaintiff's attorney would undoubtedly use such a record to develop the theory that no care whatsoever was given to the patient during this time interval, and that the patient was abandoned.

Monitoring notations in the medical record are considered inadequate when they do not offer insight into the patient's clinical status. Thus, any monitoring note for a patient who must be restrained in the ED for a lengthy period of evaluation, observation, or until an inpatient bed becomes available must include specific clinical data and observations (laboratory results, radiographic findings, hemodynamic changes, and infusion of medications and solutions). All of these deficiencies would undoubtedly be noticed and highlighted at trial by a plaintiff's expert, who frequently is a board-certified physician in the same specialty.

Documentation supporting the restraint of an impaired patient against his or her will must include a clinical description to support such a forcible impediment to the patient's right to liberty and freedom of movement. Such a clinical description should specifically describe any manifestation of agitation and uncooperative behavior. The record should refer to the specific uncooperative acts of the patient and, most importantly, should comment on the difficulties in providing care to the patient because of the patient's actions.

Physicians who order restraints for patients must exercise extreme caution in the language used to describe such patients. A judgmental note stating that a patient is "a chronic drunk and obnoxious" could undermine the support for the use of restraints. Poorly written notes can become an issue in a medical malpractice action, with the plaintiff's attorney focusing on the derogatory nature of such a statement and suggesting a less than caring attitude by the doctor toward the

patient. A plaintiff's appeal that criticizes the ethical and social consciousness of the physician could very likely be seized upon by a jury, resulting in a punitive verdict against the physician. As a general rule, all health care professionals should depict a compassionate and professional manner when describing patient behavior and lifestyles in objective and concrete terms. An alternative and more appropriate description of a patient comparable with the one above would note that the patient had a "history of alcohol dependence and was agitated and or combative."

To summarize, a well documented ED record consistent with the accepted risk management principles set forth is the best course for the physician managing a difficult overdose situation in which legal principles may appear to present problems in providing proper medical management.

FORCIBLE RESTRAINT OF THE IMPAIRED PATIENT

Patient 3

A 31 year-old woman was found unresponsive on the street and brought to the ED by ambulance. Friends on the scene reported that the patient used methadone. In the ED she was unresponsive and apneic. Oxygen was immediately administered by bag-valve mask and intravenous access was obtained. Naloxone was administered, and shortly thereafter the patient regained consciousness. After 20 minutes of care in the ED, the patient became fully alert and oriented, with no evidence of hypoxia or other clinical signs to suggest impaired judgment. The patient stated that she had taken methadone and demanded to be discharged immediately.

The right of a hospital to retain and physically restrain a person who has an altered level of consciousness for evaluation and emergency intervention is generally well supported by states and case law.¹¹ Reasonably clear guidelines for the management of such impaired patients have evolved from legal precedents governing appropriate medical assessment, from risk management considerations, and from the predictability of patient injury in the event of premature discharge.

A staff decision to allow a treated or partially treated patient with a drug overdose who subsequently becomes alert to return to the community must be based on an assessment of several factors. The initial concern is the capacity of the patient to comprehend. Before the patient can be permitted to leave the hospital, a determination would have to be made that the patient is capable of understanding the information presented and has neither a medical nor a psychiatric problem preventing such a voluntary decision. The next consideration is that of medical stability. Has the initial process that caused the clinical scenario completed its course? The history of drug use in this patient is cause for concern that the underlying toxic metabolic process is not yet resolved, and alteration in mental status, significant respiratory compromise, or other medical symptoms may recur when the naloxone is metabolized, again placing the patient at risk.

Common ED practice and sound legal principles suggest that both the hospital and its staff have a duty to prevent such a person from leaving if the duration of the effect of the involved xenobiotic is longer than that expected for the antidote. Because the duration of effect for naloxone is considerably shorter than that of methadone, the physician can predict with reasonable certainty that coma or apnea will reoccur in the near future. The physician has the duty to inform the individual of the life-threatening nature of the condition, and then to retain, with restraints if necessary to retain, the patient in the hospital until medically stable.

Liability in this situation is further reduced when the chart substantiates the medical judgment that was the basis for the decision to retain the patient and, if applicable, the use of restraints. Such documentation should specifically note the likely relapse of the patient into a symptomatic state and that this occurrence could place the patient in a life-threatening situation. When documented in a clear manner, legal challenges to the decision to restrain the patient have a limited chance of success. Sound risk management principles support treatment and detainment. Conversely, prematurely releasing a patient with a significant overdose exposes both the physician and the hospital to a claim of negligence on the grounds of failure to foresee a likely and harmful event.

BLOOD ALCOHOL CONCENTRATION AND EVIDENCE COLLECTION

Patient 4

A 41 year-old man who was a driver involved in a motor vehicle collision was taken to the ED by ambulance. Two motorists in another vehicle were killed. The patient had no physical complaints, but was brought to the hospital for medical clearance. On arrival, he was alert and oriented, responded appropriately to all commands, and demonstrated normal motor function and had a normal gait. Police officers suspected that he was driving while intoxicated, but he refused a breath alcohol test at the scene.

The police officers informed the ED staff that he was arrested and might be charged with vehicular homicide. The officers then requested that the emergency physician draw a blood specimen to determine the blood alcohol concentration. The patient stated that he would not allow the ED staff to draw blood for a determination of an alcohol concentration.

In 2010, there were 10,228 people who died in alcohol-related motor vehicle crashes, which was 31% of all traffic

related deaths in the United States.⁹ This number has declined in recent years and has decreased 4.9% from 2009. In the United States, an alcohol-related motor vehicle crash kills someone every 51 minutes.⁹ In 2010, crashes resulting from alcohol-induced impairment were responsible for 17% of fatalities in children younger than 14 years who were killed in motor vehicle crashes.⁹ Alcohol-impaired motor vehicle crashes cost more than \$37 billion every year.⁸ Drugs other than alcohol (eg, marijuana and cocaine) are involved in about 18% of motor vehicle driver fatalities.¹⁵ The judicial system has historically been one of the most effective tools to combat drunk driving, and its effectiveness depends on the ability to identify and punish individuals who violate the law. It is essential, however, that the collection of evidence does not violate the rights afforded by the US Constitution. Does forced phlebotomy for patients suspected of driving while intoxicated violate these protected rights? This has long been debated in the courts, and issues specifically brought into question include the Fourth Amendment,³⁰ the right against unreasonable search and seizure; the Fifth Amendment,³¹ the right against self-incrimination, and the Due Process clause of the Fourteenth Amendment.³² Past decisions on these issues help guide current laws and practices.

Every state, and the District of Columbia, has driver “implied consent” laws. When a person obtains a driver’s license, he or she consents at the time of acquisition to a chemical alcohol test if suspected of driving while intoxicated. Under implied consent laws, when a person suspected of driving while intoxicated refuses to take an alcohol test, a penalty is imposed. Specific penalties for refusals vary from state to state. At a minimum, the refusal results in suspension or revocation of a driver’s license. Some states assign additional fines and penalties for this action. A few states allow the refusal itself to be submitted at trial in support of the prosecution, making it possible to be convicted of an intoxication charge without chemical evidence.³ Certain states (eg, Texas, Illinois) allow blood tests to be performed on patients as ordered by an officer of the law, when there is probable cause of driving while intoxicated resulting in severe injury.^{20,28} Other states, such as New York and California, allow forced blood samples with a warrant issued by a judge.^{5,18} State laws regarding the approach to this situation vary and it is important that the ED staff be familiar with the specific requirements of the law of that state.

How much force may be used to collect chemical evidence? Does a physician violate human dignity and privacy in obtaining evidence for the State? These issues were addressed by the United States Supreme Court. In *Rochin v California*,²³ the Court overturned a conviction of drug possession based on violation of the Fourteenth Amendment. In this case, police were informed that Rochin was selling drugs. While entering the home of the defendant, the police witnessed the defendant swallow two pills that were lying on the night stand. When the officers failed to recover the pills on the scene, the officers took Rochin to the ED, where they directed the physician to administer an emetic through a nasogastric tube. The capsules were recovered from the vomit, and Rochin was convicted by the trial court for possessing morphine.^{1,23} The Supreme Court reversed this decision, based on the Fourteenth Amendment, “nor shall any State deprive any person of life, liberty or property, without due process of law....”³⁶ The term due process is vague, and is defined on a case-by-case basis, but it essentially means that states must use fair legal procedures when depriving an individual of life, liberty, or property. In *Rochin*, the court concluded that forced emesis by a physician was believed to violate Due Process, stating:

This is conduct that shocks the conscience. Illegally breaking into the privacy of the petitioner, the struggle to open his mouth and remove what was there, the forcible extraction of stomach contents—this course of proceeding by agents of government to obtain evidence is bound to offend even hardened sensibilities. They are methods too close to the rack and the screw to permit constitutional differentiation.²³

The Supreme Court revisited the issues presented in *Rochin* 4 years later in *Breithaupt v Abram*.⁴ *Breithaupt* was the driver of a truck who killed three occupants of another vehicle. In the ED, a police officer requested that a blood alcohol concentration be drawn. The blood, drawn while the patient was unconscious, was above the legal limit for alcohol and the patient was convicted of involuntary manslaughter. *Breithaupt* argued that the blood draw, as in forced emesis in *Rochin*, violated due process as he did not consent to its collection. Justice Clark disagreed, stating “the distinction rests on the fact that there is nothing ‘brutal’ or ‘offensive’ when done, as in this case, under the protective eye of a physician” and that the “blood test procedure has become routine in our everyday life.”^{3,4} Phlebotomy while the patient is unconscious and unable to give consent was determined not to violate the due process clause of the Fourteenth Amendment.

The Supreme Court continued to expand the scope of permissible phlebotomy in *Schmerber v California*.²⁵ *Schmerber* was involved in a motor vehicle crash in which the police officer suspected he was intoxicated. Unlike in *Breithaupt*, *Schmerber* was conscious, and a physician drew a blood sample at the officer’s request despite the patient’s verbal refusal. The attorney for *Schmerber* asserted that forced phlebotomy violated several constitutional rights. Specifically, it violated the Fourth, Fifth, and Fourteenth Amendments of the US Constitution. He alleged that forced phlebotomy denied him due process of the law, it violated his privilege against self-incrimination, and it violated his right against unreasonable search and seizure.^{3,25}

The Supreme Court rejected all of these arguments. The phlebotomy did not violate the due process clause because “the extraction was made by a physician in a simple, medically acceptable manner in a hospital environment. ... We cannot see that it should make any difference whether one states unequivocally that he objects or resorts to physical violence in protest or is in such condition that he is unable to protest.”²⁵ Furthermore, the forced blood draw did not violate the Fifth

Amendment's Privilege Against Self-Incrimination because the Fifth Amendment only protects evidence of a "testimonial or communicative nature," such as writings or speech. Finally, there was no violation of the Fourth and Fourteenth Amendments' protections against unreasonable search and seizure as the delay necessary to obtain a warrant threatened the destruction of evidence. Considering the "totality of the circumstances" in *Schmerber*, the blood alcohol test fell under the Court's exigent circumstances exception to the general requirement of a warrant.

The percentage of alcohol in the blood begins to diminish shortly after drinking stops, as the body functions to eliminate it from the system. Particularly in a case such as this, where time had to be taken to bring the accused to a hospital and to investigate the scene of the accident, there was no time to seek out a magistrate and secure a warrant.

To ensure compliance with standards set forth in *Schmerber*, the states have tailored laws and regulations governing the seizure of blood for the purpose of blood alcohol testing. Laws generally require the procedure be (1) performed in a reasonable, medically approved manner, (2) incident to a lawful arrest, and (3) based on the belief that the arrestee is intoxicated. It should be remembered that the issues raised by any one case are complex, and the application in real situations is difficult. Laws and regulations governing blood draws for alcohol testing vary from state to state and are the subject of frequent restructuring and amendment. Medical staff should review with hospital counsel the local laws and regulations that pertain to these issues. However, physician and patient safety must always be the priority. The benefits of determining a patient's blood alcohol concentration must be weighed against the risks of the procedure. For example, drawing blood in an agitated patient may place the staff at risk for a needle stick and the patient at risk of vascular injury.

It should also be noted that the US Supreme Court in *Missouri v. McNeely* restricted the holding of *Schmerber* for warrantless blood alcohol testing.¹⁷ In *McNeely*, the State of Missouri argued that the metabolism of alcohol over time, by itself, was justification to obtain warrantless blood alcohol testing in the hospital. The US Supreme Court rejected this argument. While the dissipation of alcohol from the blood stream over time is one of the factors to consider when evaluating the "totality of the circumstances," it does not meet the exigency exception to the warrant requirement by itself. The majority opinion held that "when officers in drunk driving investigations can reasonably obtain a warrant before having a blood sample drawn without significantly undermining the efficacy of the search, the Fourth Amendment mandates that they do so." This does not suggest that a physician should insist on a warrant when an officer requests a blood alcohol test, as this is a protection that is afforded retrospectively by the courts. Familiarity with local regulations is necessary to properly manage requests for blood alcohol testing.

CONFIDENTIALITY

Patient 5

A 32 year-old woman was fired from her job as a high school mathematics teacher. The school board called for her termination after learning that she had a history of alcohol dependence and had a previous hospitalization for detoxification at the local community hospital. A parent on the school board was also employed as a nurse at the hospital, where the teacher had received therapy. The school board member (and nurse) had inadvertently accessed the medical record of the teacher while caring for a patient with the same last name.

The Health Insurance Portability and Accountability Act (HIPAA) was enacted by Congress in 1996 and signed by President Clinton. Initially, the purpose of HIPAA was to increase the portability of health insurance, and allow employees to maintain insurance when they changed jobs. The Act called for the establishment of several provisions, among them an electronic database designed to facilitate the exchange of information between health care professionals, insurance companies, and those involved in financial and administrative transactions.¹⁶ However, the idea of developing an electronic database brought to light already growing concerns regarding the maintenance of patient privacy. For the first time, medical records would be accessible to an unlimited number of people working in health care, from bill processors to pharmacists to clinicians. Could the right to privacy be jeopardized by a system designed to increase efficiency?

Prior to HIPAA, individual hospitals or physician offices designed their own methods for maintaining confidential patient information. Records were maintained on computers in some circumstances and on paper in others. Accessibility to that information was largely regulated by state laws, and supported by some federal regulations and ethical codes of conduct. During the 1990s, however, the weaknesses of the existing systems gained attention as multiple high profile breeches of confidentiality surfaced. For example, the medical records of a congresswoman were released to the media during her campaign, making her history of depression and a past suicide attempt public knowledge.²⁶ There were also several cases of the medical records of hospital employees being read by staff members not involved in the employees' care, health insurance companies releasing health care information to employers without permission, and physicians releasing information to pharmaceutical companies that subsequently solicited the patient.³⁷ These breaches of ethics were each a testament to the fact that the right to privacy needed more stringent regulation. If these examples could occur in the previous systems for recording information, then it could be assumed that further violations would occur with increased access through an electronic database.

The Privacy Rule of HIPAA has become the most well-publicized aspect of this Act among health care personnel. The

Privacy Rule governs the use and disclosure of protected health information in the hands of health care professionals, health plans, and health care clearinghouses.¹⁶ The terminology used in the Privacy Rule is extensively defined. The following is a brief summary of the terms used.

Protected Health Information

Protected health information includes any individually identifiable information concerning the past, present, or future health of an individual; medical information pertaining to assessment and treatment of an individual; in addition to payment and billing information. All forms of information, written, oral, or electronic, are protected by this rule. Deidentified data are not considered protected health information.

Covered Entities

The term “covered entities” includes any person or business that provides health-related services or products. All those providing health-related services, for example, clinicians, pharmacists, medical equipment providers, and other health care professionals, are considered covered entities. Companies that provide disability insurance, car insurance, or casualty insurance are not included in the rule.^{16,33}

Health Care Clearinghouses

Health care clearinghouses are entities that compile health care information, such as billing companies or data processing centers.

Institutions are required to provide all individuals with written notice of their privacy policy when they first seek medical care. Patients must be informed of how the institution may use and disclose information. The notice must also describe patients’ rights, including the right to access their medical information and their right to file a complaint if they believe their rights are violated. The notice must be written in plain language, and the patient must be written acknowledgment of receipt of the information in the notice.

The Privacy Rule of HIPAA was not intended to impede health care. There are several exceptions to the rule. A covered entity is permitted to use and disclose protected health information for the purposes of evaluation and treatment. Physicians have the freedom to consult with each other, both within and outside their own institution in order to provide clinical care. Additionally, there are several specific exceptions to the Privacy Rule listed within the document—situations in which protected health information may and often must be disclosed, and may be done without an individual’s permission. For example, activities related to public health, such as reporting communicable diseases, information necessary to report actual or suspected abuse, neglect or domestic violence, or information pertaining to cadaver organ or tissue donation are specifically exempt from the Privacy Rule.¹²

The HIPAA Privacy Rule specifically addresses consultations with poison centers. It states:

We consider the counseling and follow-up consultations provided by poison control centers with individual providers regarding patient outcomes to be treatment. Therefore, poison control centers and other health care professionals can share protected health information about the treatment of an individual without a business associate contract.¹²

Violations of the Privacy Rule are subject to penalties, the severity of which is dependent on the type of infraction. Simple noncompliance may result in financial penalties. Moreover, significant or intentional disclosures of information may incur steeper fines in addition to criminal charges and potential imprisonment.³⁷ In 2009, as part of the economic stimulus, the Health Information Technology for Economic and Clinical Health Act (HITECH) under the American Recovery and Reinvestment Act (ARRA) was passed.²² This Act was primarily created to encourage the use of electronic health records and supporting technology. However, it also widened the scope of privacy and security protections defined by HIPAA. Several notable changes are the increase in civil penalties for willful neglect extending up to \$250,000 for a single violation, and as high as \$1.5 million for repeated or uncorrected violations. Furthermore, HIPAA provisions now apply to business associates. Business associates are defined as persons who, on behalf of a covered entity, perform or assist in performing a function or activity that involves the use or disclosure of individually identifiable health information.

OTHER LEGAL CONSIDERATIONS FOR POISON CENTERS AND POISON SPECIALISTS

Patient 6

The Poison Center received a call from a concerned mother that her daughter might have ingested one of the grandmother’s diabetes medications. The mother stated that the child was acting normally all day at the grandmothers’ house, but when the family returned home, the child had become drowsy. When contacted, the grandmother had confirmed that one pill was missing from her purse although she did not know the name of her medication. The poison center advised that the parents

give the child juice and closely observe her for the next 6 hours. Approximately 2 hours later, while sleeping, the child had a seizure. The child continued to seize in the hospital, where medical evaluation revealed hypoglycemia. The patient subsequently suffered permanent neurologic damage. The medication was later identified as glyburide. Action was brought against the poison center, alleging inappropriate advice and failure to recommend transport to a hospital.

As a general rule, any physician who decides to treat a patient enters into a physician–patient relationship that creates well established legal duties. Courts have ruled that the physician–patient encounter need not be a face-to-face interaction to have legal consequences. For example, the absence of physical contact between a physician and patient as in the practice of radiology and pathology does not preclude a patient from asserting that a duty of care exists.⁶ More particularly and quite relevant to the practice of a poison center, a New York State court ruled that an initial telephone call from a patient to a physician can be sufficient basis to hold that physician responsible for inappropriate advice or a significant error in judgment.¹⁹ Given the legal precedents previously stated, it is eminently clear that contact with a poison information specialist is a sufficient foundation for a subsequent legal action if inappropriate advice was given.

STANDARDS OF CARE APPLICABLE IN POISON CENTERS

Standards of care applicable to toxicologists are examined under the same legal framework as other medical specialists. The basic medical malpractice concepts are universal with some variations from state to state. Generally, for patients to prevail in medical malpractice cases, they must demonstrate “by a preponderance of the evidence: (1) that the doctor’s treatment fell below the ordinary standard of care expected of a physician in his [or her] medical specialty, and (2) the existence of a causal relationship between the alleged negligent treatment and the injury sustained.”³² While standard of care is recognized not to be one of perfection, what constitutes the “ordinary standard of care” has much room for interpretation.

In the nineteenth century, courts determined what the “ordinary standard of care” was by introducing testimony from physicians practicing in the community where the event occurred. This was known as the strict locality rule.³⁴ The strict locality rule was intended to prevent the inequities of comparing rural physicians working with limited resources and under exigent conditions from physicians working in large urban hospital settings.¹⁴ In many jurisdictions, however, the strict locality rule was rejected because (1) it was difficult to find an expert witness in a small community to testify against another physician in the community, and (2) the strict locality rule permitted some small medical communities to set unacceptably low standards of care.³⁴ In response, some states adopted the modified locality rule, which compares the physician in question with physicians practicing “in similar localities.”³⁴ Over time, the basis for the modified locality rule was also questioned. Advances in transportation, communication, and education continued to minimize the disparity between rural and urban medical practice. Many states abandoned the locality rule altogether, permitting evidence of nationwide medical practices, as described by one court:

[A] physician must exercise that degree of care, skill, and proficiency exercised by reasonably careful, skillful, and prudent practitioners in the same class to which he [or she] belongs, acting under the same or similar circumstances. Rather than focusing on different standards for different communities, this standard uses locality as but one of the factors to be considered in determining whether the doctor acted reasonably.²

While there is movement toward reviewing nationwide medical practices, depending on the jurisdiction where the event occurs, any one of the above rules may apply. In New York, courts allow evidence from the specific locality where the event occurred, from statewide practice, or from nationwide practice.¹³

A discussion of standard of care for poison control specialists should also mention several operational aspects of poison centers. Poison information specialists are required to have rapid and accurate access to a standard information resource system that contains both basic information and recommendations to deal with most toxic exposures. If a patient were to bring an action, then the negligence theory against the poison center might rely on deviations from the standard recommendations in these resources.

It would be inaccurate to suggest, however, that the duty of care owed by a poison information specialist can be measured only by how closely the advice given compares with these standard resources. Frequently, a poison specialist may encounter situations that cannot be managed in accordance with an information system alone, and may seek counsel from a clinical pharmacist or a medical toxicologist working with the poison center. If this were to occur, then any subsequent legal proceeding would also review carefully the content of the information given to the consultant regarding accuracy and appropriateness of treatment for the underlying toxicologic problem.

STATE STATUTES LIMITING LIABILITY OF POISON CONTROL CENTER CONSULTANTS

A comprehensive review of state-enacted legislation providing additional liability protection to poison center consultants is outlined elsewhere.⁷ These state statutes provide either immunity from malpractice claims or indemnity for a successful

claim against a poison center consultant. The statutes are state specific and poison center consultants should review them with local counsel, particularly if the statute has not been challenged in the jurisdiction in question.

Several states have enacted laws granting immunity to poison center consultants. Immunity is an affirmative defense to medical malpractice liability. In other words, even if a lawsuit were to meet all of the criteria for a successful malpractice claim, the lawsuit would not lead to compensation for injuries sustained because of this state-conferred protection. Examples of states that have enacted statutes providing immunity include Arkansas, California, Florida, Louisiana, Ohio, Tennessee, and Washington.¹ These statutes are not absolute protections from liability. State statutes granting immunity usually stipulate that the poison center consultant act in good faith while performing the duties required. In some instances, the poison center consultant must have been providing information in accordance with protocols established by the poison center. These laws do not protect against gross negligence, nor do they provide protection against intentional misconduct by the poison center consultant.

Other states have enacted laws that require the state to indemnify poison center consultants in the case of a successful malpractice claim. In other words, a patient may bring a medical malpractice claim against a poison center consultant, but if the claim is successful, the state itself compensates the patient rather than the poison center consultant. States that have enacted indemnity statutes, including Illinois and Texas.³⁹ Statutes providing state indemnification for medical malpractice claims are also limited in that they do not provide protection in the case of gross negligence, nor do they provide indemnity in the case of intentional misconduct.

In addition to state statutes that specifically limit liability for poison center consultants, it has been argued that some states may hypothetically provide protections under common law or general “public immunity” statutes.³⁸ Neither poison centers nor poison center consultants are specifically named under these state laws, but may be afforded immunity protection. States with general common law or “public immunity” statutes include North Carolina, Missouri, Illinois, Connecticut, and Georgia. Finally, many states have sovereign immunity statutes that afford liability protection to any entity created, funded, and operated by the state. Poison centers and their staff may be considered such an entity, and therefore, granted the protection.

PRACTICES OF REGIONAL POISON CENTERS THAT CAN REDUCE POTENTIAL LIABILITIES

There are some inherent risks of potential liability for a poison center. To minimize such risk and the risk of civil actions against a poison center, quality assurance and risk management programs should be a regular function. Daily audits or monitoring of the advice given by poison information specialists should be done. Such interactions enhance care and ensure patient safety for the individual and establish a higher general standard.

The medical toxicologists and clinical pharmacists responsible for supervising the poison information specialists must be able to adequately assess the competence and capabilities of the staff and to make recommendations, take corrective actions, and provide suggestions for improvement to involved members. This process is facilitated by such actions as audiotaping calls made to the poison center and the subsequent advice given, and reviewing written records maintained by the information specialist on each particular case. Documentation is extremely important, because in the event of a lawsuit, the most likely area of dispute will be what was actually said to the patient.

SUMMARY

- The risk management and legal issues of an ED with patients exposed to xenobiotics, often with impaired judgment, are complex. The substantial practical challenges in administering emergent treatment to an individual unable to provide proper informed consent may vary depending on individual state laws with respect to initiating that treatment.
- Medical care is further complicated by the difficulties inherent in documenting these interactions with our patients.
- Furthermore, both forcible restraint (often desired by the physician) and evidence collection (requested by law enforcement) have significant potential ramifications for the care provider.
- Maintaining patient confidentiality outside the ED, despite circumstances often visibly volatile within, may seem futile, yet legal obligations to protect patient privacy have become more stringent, not less.
- A well organized hospital is dependent on a close working relationship among the legal, risk management, and medical personnel. Only in this manner can they learn, cooperate, and meet the needs of the ever-evolving clinical dilemmas they confront.

Normal Vital Signs by Age^a

Age	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Pulse (beats/min)	Respiration (breaths/min) ^b
Adult	120	80	60–100	16–24
16 years	120	80	80	16–30
12 years	119	76	85	16–30
10 years	115	74	90	16–30
6 years	107	69	100	20–30
4 years	104	65	110	20–30
2 years	102	58	120	25–30
1 year	100	55	120	25–30
6 months	90	55	120	30
4 months	90	50	145	30–35
2 months	85	50	145	30–35
Newborn	65	50	145	35–40

^aThe normal rectal temperature is defined as 15° to 100.4° (33°–38°C) for all ages. For children 1 year of age or younger, these values are the mean values for the 50th percentile. For older children, these values represent the 90th percentile at a specific age for the 50th percentile of weight in that age group. ^bThese values were determined in the emergency department and may be environment and situation dependent.

Common Equations

<u>Temperature</u> $^{\circ}\text{C} = (^{\circ}\text{F} - 32) \times 5/9$ $^{\circ}\text{F} = (^{\circ}\text{C} \times 9/5) + 32$	<u>Weight</u> $\text{lbs} = \text{kg} \times 2.204$ $\text{kg} = \text{lbs} \times 0.454$	<u>Anion Gap (mEq/L)</u> $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$	<u>Calculated Osmolarity (mOsm/L)</u> $2\text{Na}^+ + \frac{\text{BUN}}{2.8} + \frac{\text{Glucose}}{18} + \frac{\text{EtOH}}{4.6}$	<u>SI Units from Conventional</u> $\text{mmol} = \text{mg} \div \text{MW}$ $\text{mEq} = \text{mmol} \times \text{charge}$

Toxic Syndromes

Group	Vital Signs								
	BP	P	R	T	Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
Anticholinergics	-/↑	↑	±	↑	Delirium	↑	↓	↓	Dry mucous membranes, skin flush, urinary retention
Cholinergics	±	±	-/↑	-	Normal to depressed	±	↑	↑	Salivation, lacrimation, urination, diarrhea, bronchorrhea, fasciculations, paralysis
Ethanol or sedative-hypnotics	↓	↓	↓	-/↓	Depressed	±	↓	-	Hyporeflexia, ataxia, nystagmus
Opioids	↓	↓	↓	↓	Depressed	↓	↓	-	Hyporeflexia
Sympathomimetics	↑	↑	↑	↑	Agitated, disoriented, hallucination	↑	-/↑	↑	Tremor, seizures
Withdrawal from ethanol or sedative-hypnotics	↑	↑	↑	↑	Agitated, disoriented, hallucination	↑	↑	↑	Tremor, seizures
Withdrawal from opioids (abstinence-related; antagonist precipitated withdrawal may mimic sympathomimetics)	-/↑	-/↑	-	-	Normal, anxious	↑	↑	↑	Vomiting, rhinorrhea, piloerection, diarrhea, yawning

↑ = increase, ↓ = decrease, ± = variable, - = (strongly) unlikely, BP = blood pressure, P = pulse, R = respirations, T = temperature

Selected Emergency Antidotes with Common Initial Doses^a

Antidote	Indication and Dose	Page
N-acetylcysteine	Acetaminophen: Adults: IV: 150 mg/kg in 200 mL D ₅ W infused over 60 minutes, followed by 50 mg/kg in 500 mL D ₅ W over 4 hours, then 100 mg/kg in 1000 mL D ₅ W over 16 hours. Oral: 140 mg/kg, followed by 70 mg/kg every 4 hours for 17 doses. NOTE: Special IV dilution required for children. www.acntadote.com/dosecalc.php	465
Atropine	Cholinesterase inhibitors: Adults: 1–2 mg (mild) or 3–5 mg (severe) IV, doubled every 3–5 minutes until bronchospasm resolves. Children: 20 µg/kg up to adult dose IV, doubled as for adults. Also for other cholinergics in similar dosing.	1425
L-Carnitine	Valproic acid–induced hyperammonemia or valproic acid–induced elevated AST/ALT: Clinically ill: 100 mg/kg (up to 6 g) infused IV over 30 minutes, followed by 15 mg/kg infused over 30 minutes every 6 hours. Clinically well: 100 mg/kg/day given orally in divided dose every 6 hours up to 3 g/day.	657
Deferasuxime	Iron: Begin continuous IV infusion at 5 mg/kg/h, titrate to 15 mg/kg/h as tolerated with a total dose of 6–8 g/day.	623
Digoxin-specific antibody fragments (Fab)	Digoxin: Known concentration: # of vials = wt (kg) × concentration (µg/mL) / 100 rounded up to nearest vial. Empiric dosing: Acute: 10–20 vials. Chronic: Adults: 3–6 vials; Children: 1–2 vials. Usually given as IV infusion over 30 minutes. An IV bolus is acceptable for cardiac arrest. NOTE: For nondigoxin cardioactive steroids, use empiric dose.	904
Dimercapitol (BAL)	Lead encephalopathy: 75 mg/m ² (~4 mg/kg) deep IM every 4 hours. First dose to precede edetate calcium disodium (CaNa ₂ EDTA) by 4 hours. Contraindicated if peanut allergy.	1181
Edetate calcium disodium (CaNa ₂ EDTA)	Lead encephalopathy: 1500 mg/m ² /day (~50–75 mg/kg/day) as a continuous IV infusion (conc. ≤0.5%); maximum dose 3 g/day; reduce dose if impaired kidney function. NOTE: BAL should be administered 4 hours prior to starting this dose.	1241
Fomepizole	Methanol or ethylene glycol: 15 mg/kg diluted in 100 mL 0.9% NaCl or D ₅ W infused IV over 30 minutes; after 12 hours give next 4 doses at 10 mg/kg every 12 hours; additional doses at 15 mg/kg every 12 hours if needed. Adjust dose during hemodialysis.	1364
Glucagon	β-Adrenergic antagonists or calcium channel blockers: IV infusion over 1–2 minutes. Adults and Children: 50 µg/kg. Repeat in 10 minutes for 1–2 doses as needed. Dose may be increased up to 10 mg in an adult. Consider continuous infusion at 1–5 mg/h. Emesis may occur.	870
Hydroxocobalamin	Cyanide: Adults: 5 g reconstituted with 200 mL 0.9% NaCl (invert for 60 seconds) and infuse IV over 15 minutes. Children: 70 mg/kg up to 5 g. Repeat second dose as needed.	1618
Insulin (High dose insulin [HIE] therapy)	Calcium channel blockers or β-adrenergic antagonists: 1 unit/kg IV bolus regular human insulin. Follow with infusion of 1 unit/kg/h. Use 10 units/mL insulin concentration. Titrate to 2 units/kg/h if no improvement in 15 minutes and titrate up to 10 units/kg/h as needed. If glucose <300 mg/dL, give 0.5 g/kg D ₅ W bolus. Start 0.5 g/kg/h dextrose infusion. If glucose >300 mg/dL, hold glucose. Monitor glucose every 5–30 minutes until stable then every 1–2 hours. Maintain glucose 100–250 mg/dL. Monitor K ⁺ frequently. Give K ⁺ if <2.8 mEq/L.	851
Intravenous Fat Emulsion (IFE) 20%	Cardiac arrest from lipid soluble xenobiotic (CCB, TCA, local anesthetics): IFE 20% 1.5 mL/kg over 1 minute. Follow with infusion at a rate of 0.25 mL/kg/min (15 mL/kg/h) for 30–60 minutes while continuing chest compressions. Repeat bolus for severe persistent symptoms.	931
Leucovorin (Folinic acid)	Methotrexate: 100 mg/m ² infused IV over 15–30 minutes every 3–6 hours for several days or until methotrexate serum concentration <1 × 10 ⁻⁶ M in the absence of bone marrow toxicity.	693
Methylene blue	Methemoglobinemia: 0.1–0.2 mL/kg of 1% methylene blue IV over 5 minutes followed by a 30 mL fluid flush of 0.9% sodium chloride.	1631
Naloxone	Opioid-induced respiratory depression: Adults: 40–50 µg (0.04–0.05 mg) IV titrated upward to reversal, avoid opioid withdrawal, provide manual ventilation. Children: not receiving chronic opioids 0.01 mg/kg IV titrated as for adults.	510
Nitrites and sodium thiosulfate	Cyanide: Adults: (1) Sodium nitrite: 300 mg (10 mL of a 3% conc) infused IV over 2–5 minutes. (2) Sodium thiosulfate: 12.5 g (50 mL of a 25% conc) infused IV over 10–30 minutes or as a bolus. Children: (1) Sodium nitrite: 6–8 mL/m ² (0.2 mL/kg) of a 3% conc (max 300 mg) infused IV over 2–5 minutes. (2) Sodium thiosulfate: 7 g/m ² (0.5 g/kg) (max 12.5 g) infused over 10–30 minutes or as a bolus. NOTE: In both adults and children, avoid sodium nitrite when carboxyhemoglobin is expected to be elevated.	1612
Octreotide	Sulfonylurea-induced hypoglycemia: Adults: 50 µg SQ every 6 hours. Children: 1.25 µg/kg (max 50 µg) SQ every 6 hours.	738
Physostigmine	Anticholinergic syndrome: IV infusion over 5 minutes. Adults: 1–2 mg. Children: 20 µg/kg (max 0.5 mg). The dose can be repeated in 5–10 minutes if an adequate response is not achieved and cholinergic effects are not noted.	677
Pralidoxime	Cholinesterase inhibitors: Adults: 30 mg/kg (up to 2 g) over 15–30 minutes followed by a maintenance infusion of 8–10 mg/kg/h (up to 650 mg/h) for sickest patients. Children: 30 mg/kg (max 2 g) infused IV over 15–30 minutes and then 10–20 mg/kg/h (max 650 mg/h).	1429
Pyridoxine	Isoniazid: 1 g for each gram of isoniazid up to 70 mg/kg (max 5 g) infused IV at 0.5 g/min until seizures stop, with the remainder infused IV over 4–6 hours. Empiric dose: Adults: 5 g. Children: 70 mg/kg (max 5 g) at specific dosing rate. May repeat dose if needed.	797
Succimer	Lead poisoning: Adults and Children >5 years old: 10 mg/kg orally every 8 hours for 5 days followed by every 12 hours for 14 days. Children <5 years old: 350 mg/m ² orally as for adults.	1235

^aConsult pages listed for complete information regarding dose, route, duration of therapy, adverse effects, safety issues, contraindications, and other considerations. For up-to-date information, contact your regional poison center at 800-222-1222 or a medical toxicologist.

Common Toxicology Laboratory Concentrations (serum unless otherwise noted)					
	Conventional	SI		Conventional	SI
Acetaminophen	10–30 µg/mL	66–199 µmol/L	Lithium	0.6–1.2 mEq/L	0.6–1.2 mmol/L
Arsenic (blood)	<1 µg/L	<0.0665 µmol/L	Mercury (blood)	<10 µg/L	<50 nmol/L
Arsenic (urine)	<50 µg/L	<0.665 µmol/L	Mercury (urine)	<20 µg/L	<100 nmol/L
Caffeine	1–10 µg/mL	5.2–51 µmol/L	Methanol	<25 mg/dL	<2.8 mmol/L
Carbamazepine	4–12 mg/L	17–51 µmol/L	Methemoglobin	<1%	<3%
Carboxyhemoglobin (blood)	<2%	<2%	Phenobarbital	15–40 mg/L	65–172 µmol/L
Cyanide (blood)	<1 µg/mL	<38.5 µmol/L	Phenytoin	10–20 mg/L	40–79 µmol/L
Digoxin	0.8–2 ng/mL	1.1–2.6 nmol/L	Salicylates ^a	15–30 mg/dL	1.1–2.2 mmol/L
Ethanol	80 mg/dL	17.4 mmol/L	Thallium (blood)	<2.0 µg/L	<9.78 nmol/L
Ethylene glycol	<25 mg/dL	<4 mmol/L	Thallium (urine)	<5.0 µg/L	<24.5 nmol/L
Iron	80–180 µg/dL	14–32 µmol/L	Theophylline	5–15 µg/mL	27.8–83 µmol/L
Lead (blood)	<10 µg/dL	<0.48 µmol/L	Thiocyanate	<10 µg/mL	<100 µmol/L
Lidocaine	1.5–5 µg/mL	6.4–21.4 µmol/L	Valproic acid	50–120 mg/L	347–832 µmol/L

This table provides generally accepted normal or toxication concentrations as listed. Please see the appropriate chapter for details regarding specific situations. Normal ranges may vary by laboratory.

^aThe therapeutic concentration of digoxin for heart failure is 0.5 to 0.9 ng/mL, but toxicity is usually considered only when the concentration is > 2 ng/mL. ^bThis value is the “per se” concentration for ethanol above which motor vehicle operators are considered legally impaired in the United States. ^cConcentration must be interpreted with respect to the patient’s serum pH and clinical status. ^dSee acetaminophen monograph (page 451).

Common Standard Blood/Serum Laboratory Concentrations

	Conventional	SI		Conventional	SI
Ammonia	10–80 µg/dL	6–47 µmol/L	PCO ₂ (art)	35–45 mm Hg	4.7–6.0 kPa
Bicarbonate	18–24 mEq/L	18–24 mmol/L	PCO ₂ (ven)	45–55 mm Hg	6.0–7.33 kPa
BUN	7–18 mg/dL	2.5–6.4 mmol/L	pH (art)	7.35–7.45	7.35–7.45
Calcium	8.4–10.2 mg/dL	2.10–2.55 mmol/L	pH (ven)	7.33–7.40	7.33–7.40
Chloride	98–106 mEq/L	98–106 mmol/L	PO ₂ (art)	90–100 mm Hg	12–13.3 kPa
Creatinine	0.6–1.2 mg/dL	0.053–0.106 mmol/L	PO ₂ (ven)	30–50 mm Hg	4.0–6.67 kPa
Glucose	60–110 mg/dL	3.3–6.1 mmol/L	Phosphorus	3–4.5 mg/L	1–1.4 mmol/L
Lactate	<10 mg/dL	<2 mmol/L	Potassium	3.5–5.0 mEq/L	3.5–5 mmol/L
Magnesium	1.3–2.1 mEq/L	0.65–1.05 mmol/L	Sodium	135–145 mEq/L	135–145 mmol/L

art = arterial; ven = venous.

Clinical and/or Laboratory Findings in Poisoning and Overdoses	
Agitation	Anticholinergics, ^a ethanol and sedative-hypnotic withdrawal, hypoglycemia, phencyclidine, sympathomimetics ^b
Alopecia	Alkylating agents, radiation, selenium, strontium, thallium
Ataxia	Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycemia, lithium, mercury, nitrous oxide, phenytoin
Blindness or decreased visual acuity	Caustics (direct), cocaine, cisplatin, mercury, methanol, quinine, thallium
Blue skin	Amiodarone, FD&C #1 dye, methemoglobin, silver, sulfhemoglobin
Constipation	Anticholinergics, ^a botulism, lead, opioids, thallium (severe)
Deafness, tinnitus	Aminoglycosides, cisplatin, metals, loop diuretics, opioids, quinine, salicylates
Diaphoresis	Amphetamines, cholinergics, ^c ethanol and sedative-hypnotic withdrawal, hypoglycemia, opioid withdrawal, salicylates, serotonin toxicity, sympathomimetics ^b
Diarrhea	Arsenic and other metals/metalloids, boric acid (blue-green), botanical irritants, cathartics, cholinergics, ^c colchicine, iron, lithium, opioid withdrawal, radiation
Dysesthesias, paresthesias	Acrylamide, arsenic, ciguatera, cocaine, colchicine, <i>n</i> -hexane, thallium
Gum discoloration	Arsenic, bismuth, hypervitaminosis A, lead, mercury
Hallucinations	Anticholinergics, ^a dopamine agonists, ergot alkaloids, ethanol, ethanol and sedative-hypnotic withdrawal, LSD, phencyclidine, sympathomimetics, ^b tryptamines (eg, AMT)
Headache	Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor/food interaction (hypertensive crisis), nitrites, serotonin toxicity
Metabolic acidosis (elevated anion gap)	Cyanide, ethylene glycol, ketoacidosis (diabetic, starvation, alcoholic), iron, isoniazid, metformin, methanol, paraaldehyde, phenformin, protease inhibitors, salicylates, toluene, uremia
Miosis	Cholinergics, ^c clonidine, opioids, phencyclidine, phenothiazines
Mydriasis	Anticholinergics, ^a botulism, methanol, opioid withdrawal, sympathomimetics ^b
Nystagmus	Barbiturates, carbamazepine, carbon monoxide, ethanol, lithium, monoamine oxidase inhibitors, phencyclidine, phenytoin, quinine
Purpura	Anticoagulant rodenticides, doxipogrel, corticosteroids, heparin, pit viper venom, quinine, salicylates, warfarin
Radiopaque ingestions	Arsenic, "body packer," chloral hydrate, enteric coated tablets (variable), halogenated hydrocarbons, metals (eg, iron, lead)
Red skin	Anticholinergics, ^a boric acid, disulfiram-ethanol interaction, hydroxocobalamin, scombroid, vancomycin
Rhabdomyolysis	Carbon monoxide, doxylamine, HMG CoA reductase inhibitors, sympathomimetics, ^b <i>Tricholoma</i> mushrooms
Salivation	Arsenic, caustics, cholinergics, ^c ketamine, mercury, phencyclidine
Seizures	Bupropion, camphor, carbon monoxide, cyclic antidepressants, ethanol and sedative-hypnotic withdrawal, <i>Gyromitra</i> mushrooms, hypoglycemia, isoniazid, theophylline
Tremor	Antipsychotics, arsenic, carbon monoxide, cholinergics, ^c ethanol, lithium, mercury, methyl bromide, sympathomimetics, ^b thyroid hormones
Weakness	Botulism, diuretics, magnesium, neuromuscular blockers, paralytic shellfish, steroids, toluene
Yellow skin (jaundice)	Acetaminophen (late), <i>Amanita</i> mushrooms, β -carotene, dinitrophenol, pyrrolizidine alkaloids

Anticholinergics: eg, antihistamines, atropine, cyclic antidepressants, scopolamine. ^aSympathomimetics: eg, amphetamines, β -adrenergic agents, cocaine, ephedrine, methylxanthines. ^bCholinergics: eg, muscarinic mushrooms, organic phosphorus compounds, and carbamates, including Alzheimer drugs and physostigmine and pilocarpine, and other direct acting cholinergics.
